This edition applies to IBM z/OS XL C/C++ compiler in IBM z/OS operating system Version 1 Release 13 (5694-A01) and to all subsequent releases until otherwise indicated in new editions. This edition replaces z/OS XL C/C++ Language Reference, SC09-4815-10. Make sure that you use the correct edition for the level of the program listed above. Also, ensure that you apply all necessary PTFs for the program.

IBM welcomes your comments. You can send your comments via e-mail to compinfo@ca.ibm.com. Be sure to include your e-mail address if you want a reply.

Include the title and order number of this document, and the page number or topic related to your comment. When you send information to IBM, you grant IBM a nonexclusive right to use or distribute the information in any way it believes appropriate without incurring any obligation to you.

Multiplication operator * .............................................. 134
Division operator / .................................................... 134
Remainder operator % ............................................... 135
Addition operator + .................................................. 135
Subtraction operator - ................................................ 135
Bitwise left and right shift operators << >> ......................... 136
Relational operators < > <= >= ..................................... 136
Equality and inequality operators == != ................................ 137
Bitwise AND operator & .............................................. 138
Bitwise exclusive OR operator ^ ..................................... 139
Bitwise inclusive OR operator | ..................................... 139
Logical AND operator && ............................................. 140
Logical OR operator || ................................................ 140
Array subscripting operator [ ] ..................................... 141
Vector subscripting operator [ ] (IBM extension) .................. 142
Comma operator , ..................................................... 142
Pointer to member operators .* ->* (C++ only) ....................... 144
Conditional expressions .............................................. 144
Types in conditional C expressions (C only) ......................... 145
Types in conditional C++ expressions (C++ only) .................... 145
Examples of conditional expressions ................................ 146
Cast expressions ..................................................... 146
Cast operator () ....................................................... 146
Contents

Chapter 9. Namespaces (C++ only) ................................................................. 221
  Defining namespaces ................................................................................. 221
  Declaring namespaces ............................................................................... 221
  Creating a namespace alias ...................................................................... 221
  Creating an alias for a nested namespace ................................................. 222
  Extending namespaces .............................................................................. 222
  Namespaces and overloading .................................................................... 222
  Unnamed namespaces ................................................................................ 223
  Namespace member definitions ................................................................. 224
  Namespaces and friends ........................................................................... 225
  The using directive ..................................................................................... 225
  The using declaration and namespaces ....................................................... 226
  Explicit access .......................................................................................... 227
  Inline namespace definitions (C++0x) ...................................................... 227

Chapter 10. Overloading (C++ only) ................................................................. 231
  Overloading functions ............................................................................... 231
    Restrictions on overloaded functions ..................................................... 232
  Overloading operators .............................................................................. 233
    Overloading unary operators .................................................................. 235
    Overloading increment and decrement operators .................................... 235
    Overloading binary operators .................................................................. 237
    Overloading assignments .......................................................................... 237
    Overloading function calls ...................................................................... 239
    Overloading subscripting ......................................................................... 240
    Overloading class member access ........................................................... 240
  Overload resolution .................................................................................... 241
    Implicit conversion sequences ................................................................. 242
    Resolving addresses of overloaded functions ......................................... 243

Chapter 11. Classes (C++ only) ...................................................................... 245
  Declaring class types ................................................................................ 245
  Using class objects ..................................................................................... 246
  Classes and structures ............................................................................... 248
  Scope of class names .................................................................................. 249
    Incomplete class declarations ................................................................. 249
    Nested classes .......................................................................................... 250
### Chapter 12. Class members and friends (C++ only)

- Class member lists .................................. 255
- Data members ........................................ 256
- Member functions .................................... 256
  - Inline member functions ............................ 257
  - Constant and volatile member functions ......... 258
  - Virtual member functions .......................... 258
  - Special member functions .......................... 258
- Member scope ....................................... 258
- Pointers to members ................................ 260
- The this pointer .................................... 261
- Static members ...................................... 264
  - Using the class access operators with static members 264
  - Static data members ................................ 265
  - Static member functions ........................... 267
- Member access ....................................... 268
- Friends ............................................. 270
  - Friend scope ................................... 274
  - Friend access ................................... 276

### Chapter 13. Inheritance (C++ only)

- Derivation .......................................... 278
- Inherited member access ............................ 281
  - Protected members ................................ 282
  - Access control of base class members .......... 283
- The using declaration and class members ........ 284
  - Overloading member functions from base and derived classes 285
  - Changing the access of a class member ........ 286
- Multiple inheritance ................................ 288
  - Virtual base classes .............................. 289
  - Multiple access ................................ 290
  - Ambiguous base classes ........................... 290
- Virtual functions ................................... 294
  - Ambiguous virtual function calls ............... 298
  - Virtual function access ........................... 299
- Abstract classes ................................... 299

### Chapter 14. Special member functions (C++ only)

- Overview of constructors and destructors ........ 303
- Constructors ........................................ 304
  - Default constructors ................................ 304
  - Delegating constructors (C++0x) ................ 306
  - Explicit initialization with constructors ...... 307
  - Initialization of base classes and members .... 308
  - Constructors execution order of class objects .. 312
- Destructors .......................................... 314
  - Pseudo-destructors ............................... 316
- User-defined conversions ........................... 316
  - Conversion constructors ......................... 318
  - The explicit specifier ........................... 319
  - Conversion functions ............................. 319
- Copy constructors ................................... 320
- Copy assignment operators .......................... 322
File inclusion directives .................................................. 399
The #include directive ................................................... 399
The #include_next directive (IBM extension) ....................... 401
Conditional compilation directives .................................... 401
The #if and #elif directives ............................................ 403
The #ifdef directive ..................................................... 403
The #ifndef directive .................................................... 404
The #else directive ....................................................... 404
The #endif directive ...................................................... 404
Message generation directives ......................................... 405
The #error directive ...................................................... 405
The #line directive ....................................................... 406
The null directive (#) .................................................... 407
Pragma directives ........................................................ 408
The _Pragma preprocessing operator ................................... 408
Standard pragmas (C only) ................................................ 408
C99 preprocessor features adopted in C++0x ......................... 409

About this information

This information describes the syntax, semantics, and IBM z/OS® XL C/C++ implementation of the C and C++ programming languages. Although the XL C and XL C++ compilers conform to the specifications maintained by the ISO standards for the C and C++ programming languages, the compilers also incorporate many extensions to the core languages. These extensions have been implemented with the aims of enhancing usability in specific operating environments, supporting compatibility with other compilers, and supporting new hardware capabilities. For example, on the z/OS platform, language constructs have been added to provide support for data types that are specific to the IBM® System z® environment.

Note: As of z/OS V1R7, IBM z/OS C/C++ compiler has been rebranded to IBM z/OS XL C/C++.

Who should read this information

This information is a reference for users who already have experience programming applications in C or C++. Users new to C or C++ can still use this information to find language and features unique to XL C/C++; however, this reference does not aim to teach programming concepts nor to promote specific programming practices.

How to use this information

Unless indicated otherwise, all of the text in this reference pertains to both C and C++ languages. Where there are differences between languages, these are indicated through qualifying text and other graphical elements (see below for the conventions used).

While this information covers both standard and implementation-specific features, it does not include the following topic:
• Standard C and C++ library functions and headers. For standard C/C++ library information, refer to the Standard C++ Library Reference.

How this information is organized

This information is organized to loosely follow the structure of the ISO standard language specifications and topics are grouped into similar headings.
• Chapters 3 through 10 discuss language elements that are common to both C and C++, including scope and linkage, lexical elements, data types, declarations, declarators, type conversions, expressions, operators, statements, and functions. Throughout these chapters, both standard features and extensions are discussed.
• Chapters 11 through 18 discuss standard C++ features exclusively, including classes, overloading, inheritance, templates, and exception handling.
• Chapters 19 through 22 discuss directives to the preprocessor and macros that are predefined by the compiler.
• Chapters 23 through 25 discuss the compatibility and conformance on the z/OS platform.
• The last chapters discuss implementation-defined behavior, accessibility, and notices.

Conventions

Typographical conventions

The following table explains the typographical conventions used in the information.

Table 1. Typographical conventions

<table>
<thead>
<tr>
<th>Typeface</th>
<th>Indicates</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>bold</td>
<td>Lowercase commands, executable names, compiler options, and directives.</td>
<td>The compiler provides basic invocation commands, <code>xlc</code> and <code>xlC (xlc++)</code>, along with several other compiler invocation commands to support various C language levels and compilation environments.</td>
</tr>
<tr>
<td>italics</td>
<td>Parameters or variables whose actual names or values are to be supplied by the user. Italics are also used to introduce new terms.</td>
<td>Make sure that you update the <code>size</code> parameter if you return more than the <code>size</code> requested.</td>
</tr>
<tr>
<td>underlining</td>
<td>The default setting of a parameter of a compiler option or directive.</td>
<td>`nomaf</td>
</tr>
<tr>
<td>monospace</td>
<td>Programming keywords and library functions, compiler builtins, examples of program code, command strings, or user-defined names.</td>
<td>To compile and optimize <code>myprogram.c</code>, enter: <code>xlc myprogram.c -O3</code>.</td>
</tr>
</tbody>
</table>

Qualifying elements (icons)

Most features described in this information apply to both C and C++ languages. In descriptions of language elements where a feature is exclusive to one language, or where functionality differs between languages, this information uses icons to delineate segments of text as follows:

Table 2. Qualifying elements

<table>
<thead>
<tr>
<th>Qualifier/Icon</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>C only, or C only begins</td>
<td>The text describes a feature that is supported in the C language only; or describes behavior that is specific to the C language.</td>
</tr>
<tr>
<td>C++ only, or C++ only begins</td>
<td>The text describes a feature that is supported in the C++ language only; or describes behavior that is specific to the C++ language.</td>
</tr>
<tr>
<td>IBM extension begins</td>
<td>The text describes a feature that is an IBM extension to the standard language specifications.</td>
</tr>
<tr>
<td>IBM extension ends</td>
<td>The text describes a feature that is introduced into standard C as part of C1X.</td>
</tr>
</tbody>
</table>
Table 2. Qualifying elements  (continued)

<table>
<thead>

Syntax diagrams

Throughout this information, diagrams illustrate z/OS XL C/C++ syntax. This section will help you to interpret and use those diagrams.

- Read the syntax diagrams from left to right, from top to bottom, following the path of the line.
  - The symbol indicates the beginning of a command, directive, or statement.
  - The symbol indicates that the command, directive, or statement syntax is continued on the next line.
  - The symbol indicates that a command, directive, or statement is continued from the previous line.
  - The symbol indicates the end of a command, directive, or statement.

- Fragments, which are diagrams of syntactical units other than complete commands, directives, or statements, start with the symbol and end with the symbol.

- Required items are shown on the horizontal line (the main path):
  - The symbol indicates that you must choose one of the items.
  - If you can choose from two or more items, they are shown vertically, in a stack.
  - If choosing one of the items is optional, the entire stack is shown below the main path.

- An arrow returning to the left above the main line (a repeat arrow) indicates that you can make more than one choice from the stacked items or repeat an item. The separator character, if it is other than a blank, is also indicated:

- The item that is the default is shown above the main path.

About this information  XV
• Keywords are shown in nonitalic letters and should be entered exactly as shown.
• Variables are shown in italicized lowercase letters. They represent user-supplied names or values.
• If punctuation marks, parentheses, arithmetic operators, or other such symbols are shown, you must enter them as part of the syntax.

Sample syntax diagram

The following syntax diagram example shows the syntax for the #pragma comment directive.

Notes:
1. This is the start of the syntax diagram.
2. The symbol # must appear first.
3. The keyword pragma must appear following the # symbol.
4. The name of the pragma comment must appear following the keyword pragma.
5. An opening parenthesis must be present.
6. The comment type must be entered only as one of the types indicated: compiler, date, timestamp, copyright, or user.
7. A comma must appear between the comment type copyright or user, and an optional character string.
8. A character string must follow the comma. The character string must be enclosed in double quotation marks.
9. A closing parenthesis is required.
10. This is the end of the syntax diagram.

The following examples of the #pragma comment directive are syntactically correct according to the diagram shown above:

```
#pragma comment(date)
#pragma comment(user)
#pragma comment(copyright,"This text will appear in the module")
```

Examples in this information

The examples in this information, except where otherwise noted, are coded in a simple style that does not try to conserve storage, check for errors, achieve fast performance, or demonstrate all possible methods to achieve a specific result.
z/OS XL C/C++ and related documents

z/OS XL C/C++ documents address a variety of application development tasks and are provided in multiple formats.

For a summary of the information contained in z/OS XL C/C++ documents see "z/OS XL C/C++ and related documents" in z/OS XL C/C++ User’s Guide.

Softcopy documents

The z/OS XL C/C++ documents are supplied in PDF and IBM BookMaster® formats on the following CD: z/OS Collection, SK3T-4269. They are also available at http://www.ibm.com/software/awdtools/czos/library/.

To read a PDF file, use the Adobe Reader. If you do not have the Adobe Reader, you can download it (subject to Adobe license terms) from the Adobe Web site at http://www.adobe.com.

You can also browse the documents on the World Wide Web by visiting the z/OS library at http://www.ibm.com/systems/z/os/zos/bkserv/.

Note: For further information on viewing and printing softcopy documents and using IBM BookManager®, see z/OS Information Roadmap.

Softcopy examples

For information on the labelling used to identify examples that are available as softcopy files, see "Softcopy examples" in z/OS XL C/C++ User’s Guide.

z/OS XL C/C++ on the World Wide Web

Additional information on z/OS XL C/C++ is available on the World Wide Web on the z/OS XL C/C++ home page at: http://www.ibm.com/software/awdtools/czos/

This page contains late-breaking information about the z/OS XL C/C++ product, including the compiler, the C/C++ libraries, and utilities. There are links to other useful information, such as the z/OS XL C/C++ information library and the libraries of other z/OS elements that are available on the Web. The z/OS XL C/C++ home page also contains links to other related Web sites.

Technical support

Additional technical support is available from the z/OS XL C/C++ Support page. This page provides a portal with search capabilities to a large selection of technical support FAQs and other support documents. You can find the z/OS XL C/C++ Support page on the Web at: http://www.ibm.com/software/awdtools/czos/support/

If you cannot find what you need, you can e-mail:

compinfo@ca.ibm.com

For the latest information about z/OS XL C/C++, visit the product information site at: http://www.ibm.com/software/awdtools/czos

For information about boosting performance, productivity and portability, visit the C/C++ Cafe at: http://www-949.ibm.com/software/rational/cafe/community/ccpp

How to send your comments

Your feedback is important in helping to provide accurate and high-quality information. If you have any comments about this document or any other z/OS XL C/C++ documentation, send your comments by e-mail to:

compinfo@ca.ibm.com

Be sure to include the name of the document, the part number of the document, the version of, and, if applicable, the specific location of the text you are commenting on (for example, a page number or table number).

When you send information to IBM, you grant IBM a nonexclusive right to use or distribute the information in any way it believes appropriate without incurring any obligation to you.
Chapter 1. Scope and linkage

Scope is the largest region of program text in which a name can potentially be used without qualification to refer to an entity; that is, the largest region in which the name is potentially valid. Broadly speaking, scope is the general context used to differentiate the meanings of entity names. The rules for scope combined with those for name resolution enable the compiler to determine whether a reference to an identifier is legal at a given point in a file.

The scope of a declaration and the visibility of an identifier are related but distinct concepts. Scope is the mechanism by which it is possible to limit the visibility of declarations in a program. The visibility of an identifier is the region of program text from which the object associated with the identifier can be legally accessed. Scope can exceed visibility, but visibility cannot exceed scope. Scope exceeds visibility when a duplicate identifier is used in an inner declarative region, thereby hiding the object declared in the outer declarative region. The original identifier cannot be used to access the first object until the scope of the duplicate identifier (the lifetime of the second object) has ended.

Thus, the scope of an identifier is interrelated with the storage duration of the identified object, which is the length of time that an object remains in an identified region of storage. The lifetime of the object is influenced by its storage duration, which in turn is affected by the scope of the object identifier.

Linkage refers to the use or availability of a name across multiple translation units or within a single translation unit. The term translation unit refers to a source code file plus all the header and other source files that are included after preprocessing with the #include directive, minus any source lines skipped because of conditional preprocessing directives. Linkage allows the correct association of each instance of an identifier with one particular object or function.

Scope and linkage are distinguishable in that scope is for the benefit of the compiler, whereas linkage is for the benefit of the linker. During the translation of a source file to object code, the compiler keeps track of the identifiers that have external linkage and eventually stores them in a table within the object file. The linker is thereby able to determine which names have external linkage, but is unaware of those with internal or no linkage.

The distinctions between the different types of scopes are discussed in “Scope.” The different types of linkages are discussed in “Program linkage” on page 6.

Chapter 9, “Namespaces (C++ only),” on page 221

Scope

The scope of an identifier is the largest region of the program text in which the identifier can potentially be used to refer to its object. In C++, the object being referred to must be unique. However, the name to access the object, the identifier itself, can be reused. The meaning of the identifier depends upon the context in which the identifier is used. Scope is the general context used to distinguish the meanings of names.

The scope of an identifier is possibly noncontiguous. One of the ways that breakage occurs is when the same name is reused to declare a different entity, thereby creating a contained declarative region (inner) and a containing declarative region (outer). Thus, point of declaration is a factor affecting scope. Exploiting the possibility of a noncontiguous scope is the basis for the technique called information hiding.

The concept of scope that exists in C was expanded and refined in C++. The following table shows the kinds of scopes and the minor differences in terminology.
Table 3. Kinds of scope

<table>
<thead>
<tr>
<th>C</th>
<th>C++</th>
</tr>
</thead>
<tbody>
<tr>
<td>block</td>
<td>[local]</td>
</tr>
<tr>
<td>function</td>
<td>function</td>
</tr>
<tr>
<td>Function prototype</td>
<td>Function prototype</td>
</tr>
<tr>
<td>file</td>
<td>namespace</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>class</td>
</tr>
</tbody>
</table>

In all declarations, the identifier is in scope before the initializer. The following example demonstrates this:

```c
int x;
void f() {
    int x = x;
}
```

The x declared in function f() has local scope, not global scope.

Chapter 9, “Namespaces (C++ only),” on page 221

### Block/local scope

A name has local scope or block scope if it is declared in a block. A name with local scope can be used in that block and in blocks enclosed within that block, but the name must be declared before it is used. When the block is exited, the names declared in the block are no longer available.

Parameter names for a function have the scope of the outermost block of that function. Also, if the function is declared and not defined, these parameter names have function prototype scope.

When one block is nested inside another, the variables from the outer block are usually visible in the nested block. However, if the declaration of a variable in a nested block has the same name as a variable that is declared in an enclosing block, the declaration in the nested block hides the variable that was declared in the enclosing block. The original declaration is restored when program control returns to the outer block. This is called block visibility.

Name resolution in a local scope begins in the immediately enclosing scope in which the name is used and continues outward with each enclosing scope. The order in which scopes are searched during name resolution causes the phenomenon of information hiding. A declaration in an enclosing scope is hidden by a declaration of the same identifier in a nested scope.

“Block statements” on page 165

### Function scope

The only type of identifier with function scope is a label name. A label is implicitly declared by its appearance in the program text and is visible throughout the function that declares it.

A label can be used in a goto statement before the actual label is seen.
Related reference

"Labeled statements" on page 163

Function prototype scope

In a function declaration (also called a function prototype) or in any function declarator—except the declarator of a function definition—parameter names have function prototype scope. Function prototype scope terminates at the end of the nearest enclosing function declarator.

Related reference

"Function declarations" on page 185

File/global scope

C A name has file scope if the identifier's declaration appears outside of any block. A name with file scope and internal linkage is visible from the point where it is declared to the end of the translation unit.

C++ Global scope or global namespace scope is the outermost namespace scope of a program, in which objects, functions, types and templates can be defined. A name has global namespace scope if the identifier's declaration appears outside of all blocks, namespaces, and classes.

A name with global namespace scope and internal linkage is visible from the point where it is declared to the end of the translation unit.

A name with global (namespace) scope is also accessible for the initialization of global variables. If that name is declared extern, it is also visible at link time in all object files being linked.

A user-defined namespace can be nested within the global scope using namespace definitions, and each user-defined namespace is a different scope, distinct from the global scope.

“Internal linkage” on page 7

Examples of scope in C

The following example declares the variable x on line 1, which is different from the x it declares on line 2. The declared variable on line 2 has function prototype scope and is visible only up to the closing parenthesis of the prototype declaration. The variable x declared on line 1 resumes visibility after the end of the prototype declaration.

```
1 int x = 4;    /* variable x defined with file scope */
2 long myfunc(int x, long y); /* variable x has function */
3    /* prototype scope */
4 int main(void)
5 {
6    /* . . . */
7 }
```

The following program illustrates blocks, nesting, and scope. The example shows two kinds of scope: file and block. The main function prints the values 1, 2, 3, 0, 3, 2, 1 on separate lines. Each instance of i represents a different variable.
Class scope (C++ only)

A name declared within a member function hides a declaration of the same name whose scope extends to or past the end of the member function's class.

When the scope of a declaration extends to or past the end of a class definition, the regions defined by the member definitions of that class are included in the scope of the class. Members defined lexically outside of the class are also in this scope. In addition, the scope of the declaration includes any portion of the declarator following the identifier in the member definitions.

The name of a class member has class scope and can only be used in the following cases:

- In a member function of that class
- In a member function of a class derived from that class
- After the . (dot) operator applied to an instance of that class
- After the . (dot) operator applied to an instance of a class derived from that class, as long as the derived class does not hide the name
- After the -> (arrow) operator applied to a pointer to an instance of that class
- After the -> (arrow) operator applied to a pointer to an instance of a class derived from that class, as long as the derived class does not hide the name
- After the :: (scope resolution) operator applied to the name of a class
- After the :: (scope resolution) operator applied to a class derived from that class

```c
#include <stdio.h>
int i = 1; /* i defined at file scope */

int main(int argc, char * argv[]) {
  printf("%d
", i); /* Prints 1 */
  {
    int i = 2, j = 3; /* i and j defined at block scope */
    /* global definition of i is hidden */
    printf("%d
%d
", i, j); /* Prints 2, 3 */
    {
      int i = 0; /* i is redefined in a nested block */
      /* previous definitions of i are hidden */
      printf("%d
%d
", i, j); /* Prints 0, 3 */
    }
    printf("%d
", i); /* Prints 2 */
    printf("%d
", i); /* Prints 1 */
  }
  return 0;
}
```

```c
#include <stdio.h>
int i = 1; /* i defined at file scope */

int main(int argc, char * argv[]) {
  printf("%d
", i); /* Prints 1 */
  {
    int i = 2, j = 3; /* i and j defined at block scope */
    /* global definition of i is hidden */
    printf("%d
%d
", i, j); /* Prints 2, 3 */
    {
      int i = 0; /* i is redefined in a nested block */
      /* previous definitions of i are hidden */
      printf("%d
%d
", i, j); /* Prints 0, 3 */
    }
    printf("%d
", i); /* Prints 2 */
    printf("%d
", i); /* Prints 1 */
  }
  return 0;
}```
Namespaces of identifiers

Namespaces are the various syntactic contexts within which an identifier can be used. Within the same context and the same scope, an identifier must uniquely identify an entity. Note that the term namespace as used here applies to C as well as C++ and does not refer to the C++ namespace language feature. The compiler sets up namespaces to distinguish among identifiers referring to different kinds of entities. Identical identifiers in different namespaces do not interfere with each other, even if they are in the same scope.

The same identifier can declare different objects as long as each identifier is unique within its namespace. The syntactic context of an identifier within a program lets the compiler resolve its namespace without ambiguity.

Within each of the following four namespaces, the identifiers must be unique:

- **Tags** of the following types must be unique within a single scope:
  - Enumerations
  - Structures and unions
- **Members** of structures, unions, and classes must be unique within a single structure, union, or class type.
- **Statement labels** have function scope and must be unique within a function.
- All other **ordinary identifiers** must be unique within a single scope:
  - C function names (C++ function names can be overloaded)
  - Variable names
  - Names of function parameters
  - Enumeration constants
  - typedef names

You can redefine identifiers in the same namespace using enclosed program blocks.

Structure tags, structure members, variable names, and statement labels are in four different namespaces. No name conflict occurs among the items named student in the following example:

```c
int get_item()
{
    struct student /* structure tag */
    {
        char student[20]; /* structure member */
        int section;
        int id;
    } student; /* structure variable */

    goto student;
    student::; /* null statement label */
    return 0;
}
```
The compiler interprets each occurrence of student by its context in the program: when student appears after the keyword struct, it is a structure tag; when it appears in the block defining the student type, it is a structure member variable; when it appears at the end of the structure definition, it declares a structure variable; and when it appears after the goto statement, it is a label.

**Name hiding (C++ only)**

If a class name or enumeration name is in scope and not hidden, it is visible. A class name or enumeration name can be hidden by an explicit declaration of that same name — as an object, function, or enumerator — in a nested declarative region or derived class. The class name or enumeration name is hidden wherever the object, function, or enumerator name is visible. This process is referred to as name hiding.

In a member function definition, the declaration of a local name hides the declaration of a member of the class with the same name. The declaration of a member in a derived class hides the declaration of a member of a base class of the same name.

Suppose a name x is a member of namespace A, and suppose that the members of namespace A are visible in namespace B through the use of a declaration. A declaration of an object named x in namespace B will hide A::x. The following example demonstrates this:

```c++
#include <iostream>
#include <typeinfo>
using namespace std;

namespace A {
    char x;
};

namespace B {
    using namespace A;
    int x;
};

int main() {
    cout << typeid(B::x).name() << endl;
}
```

The following is the output of the above example:

```text
int
```

The declaration of the integer x in namespace B hides the character x introduced by the using declaration.

**Program linkage**

Linkage determines whether identifiers that have identical names refer to the same object, function, or other entity, even if those identifiers appear in different translation units. The linkage of an identifier depends on how it was declared. There are three types of linkages:

- **Internal linkage** on page 7: identifiers can only be seen within a translation unit.
- **External linkage** on page 7: identifiers can be seen (and referred to) in other translation units.
- **No linkage** on page 8: identifiers can only be seen in the scope in which they are defined.
Linkage does not affect scoping, and normal name lookup considerations apply.

You can also have linkage between C++ and non-C++ code fragments, which is called language linkage. Language linkage enables the close relationship between C++ and C by allowing C++ code to link with that written in C. All identifiers have a language linkage, which by default is C++. Language linkage must be consistent across translation units, and non-C++ language linkage implies that the identifier has external linkage.

**Related reference**

- “The static storage class specifier” on page 45
- “The extern storage class specifier” on page 46
- “Function storage class specifiers” on page 189
- “Type qualifiers” on page 74
- Anonymous unions

### Internal linkage

The following kinds of identifiers have internal linkage:

- Objects, references, or functions explicitly declared `static`
- Objects or references declared in namespace scope (or global scope in C) with the specifier `const` and neither explicitly declared `extern`, nor previously declared to have external linkage
- Data members of an anonymous union
- Function templates explicitly declared `static`
- Identifiers declared in the unnamed namespace

A function declared inside a block will usually have external linkage. An object declared inside a block will usually have external linkage if it is specified `extern`. If a variable that has `static` storage is defined outside a function, the variable has internal linkage and is available from the point where it is defined to the end of the current translation unit.

If the declaration of an identifier has the keyword `extern` and if a previous declaration of the identifier is visible at namespace or global scope, the identifier has the same linkage as the first declaration.

### External linkage

In global scope, identifiers for the following kinds of entities declared without the `static` storage class specifier have external linkage:

- An object
- A function

If an identifier in C is declared with the `extern` keyword and if a previous declaration of an object or function with the same identifier is visible, the identifier has the same linkage as the first declaration. For example, a variable or function that is first declared with the keyword `static` and later declared with the keyword `extern` has internal linkage. However, a variable or function that has no linkage and was later declared with a linkage specifier will have the linkage that was expressly specified.

In namespace scope, the identifiers for the following kinds of entities have external linkage:

- A reference or an object that does not have internal linkage
- A function that does not have internal linkage
- A named class or enumeration
- An unnamed class or enumeration defined in a typedef declaration
- An enumerator of an enumeration that has external linkage
A template, unless it is a function template with internal linkage
A namespace, unless it is declared in an unnamed namespace

If the identifier for a class has external linkage, then, in the implementation of that class, the identifiers for the following will also have external linkage:
A member function
A static data member
A class of class scope
An enumeration of class scope

"The _Export qualifier (C++ only)" on page 105
"The _Export function specifier (C++ only)" on page 197

No linkage

The following kinds of identifiers have no linkage:
Names that have neither external or internal linkage
Names declared in local scopes (with exceptions like certain entities declared with the \texttt{extern} keyword)
Identifiers that do not represent an object or a function, including labels, enumerators, typedef names that refer to entities with no linkage, type names, function parameters, and template names

You cannot use a name with no linkage to declare an entity with linkage. For example, you cannot use the name of a structure or enumeration or a typedef name referring to an entity with no linkage to declare an entity with linkage. The following example demonstrates this:

```cpp
int main() {
    struct A { };  
    // extern A a1;
    typedef A myA;
    // extern myA a2;
}
```

The compiler will not allow the declaration of \texttt{a1} with external linkage. Structure \texttt{A} has no linkage. The compiler will not allow the declaration of \texttt{a2} with external linkage. The typedef name \texttt{myA} has no linkage because \texttt{A} has no linkage.

Language linkage (C++ only)

Linkage between C++ and non-C++ code fragments is called \textit{language linkage}. All function types, function names, and variable names have a language linkage, which by default is C++.

You can link C++ object modules to object modules produced using other source languages such as C by using a \textit{linkage specification}.

\textbf{Linkage specification syntax}

```
// extern string_literal declaration
```

z/OS V1R13.0 XL C/C++ Language Reference
The string_literal is used to specify the linkage associated with a particular function. String literals used in linkage specifications should be considered as case-sensitive. All platforms support the following values for string_literal:

"C++" Unless otherwise specified, objects and functions have this default linkage specification.

"C" Indicates linkage to a C procedure.

Calling shared libraries that were written before C++ needed to be taken into account requires the #include directive to be within an extern "C" {} declaration.

extern "C" {
#include "shared.h"
}

The following example shows a C printing function that is called from C++.

// in C++ program
extern "C" int displayfoo(const char *);
int main() {
    return displayfoo("hello");
}

/* in C program */
#include <stdio.h>
extern int displayfoo(const char * str) {
    while (*str) {
        putchar(*str);
        putchar(' ');
        ++str;
    }
    putchar('
');
}

CCNX02J
// This example illustrates linkage specifications.

extern "C" int printf(const char*,...);

int main(void) {
    printf("hello\n");
}

Here the string_literal "C" tells the compiler that the routine printf(const char*,...) is a C function.

Note: This example is not guaranteed to work on all platforms. The only safe way to declare a C function in a C++ program is to include the appropriate header. In this example you would substitute the line of code with extern with the following line:

#include <stdio.h>

Name mangling (C++ only)

Name mangling is the encoding of function and variable names into unique names so that linkers can separate common names in the language. Type names may also be mangled. Name mangling is commonly used to facilitate the overloading feature and visibility within different scopes. The compiler generates function names with an encoding of the types of the function arguments when the module is compiled. If a variable is in a namespace, the name of the namespace is mangled into the variable name so that the same variable name can exist in more than one namespace. The C++ compiler also mangles C variable names to identify the namespace in which the C variable resides.
The scheme for producing a mangled name differs with the object model used to compile the source code: the mangled name of an object of a class compiled using one object model will be different from that of an object of the same class compiled using a different object model. The object model is controlled by compiler option or by pragma.

Name mangling is not desirable when linking C modules with libraries or object files compiled with a C++ compiler. To prevent the C++ compiler from mangling the name of a function, you can apply the extern "C" linkage specifier to the declaration or declarations, as shown in the following example:

```c
extern "C" {
    int f1(int);
    int f2(int);
    int f3(int);
};
```

This declaration tells the compiler that references to the functions f1, f2, and f3 should not be mangled.

The extern "C" linkage specifier can also be used to prevent mangling of functions that are defined in C++ so that they can be called from C. For example,

```c
extern "C" {
    void p(int){
        /* not mangled */
    }
};
```

In multiple levels of nested extern declarations, the innermost extern specification prevails.

```c
extern "C" {
    extern "C++" {
        void func();
    }
}
```

In this example, func has C++ linkage.

Chapter 2. Lexical Elements

A lexical element refers to a character or groupings of characters that may legally appear in a source file. This topic contains discussions of the basic lexical elements and conventions of the C and C++ programming languages.

Tokens

Source code is treated during preprocessing and compilation as a sequence of tokens. A token is the smallest independent unit of meaning in a program, as defined by the compiler. There are four different types of tokens:

- Keywords
- Identifiers
- Literals
- Punctuators and operators

Adjacent identifiers, keywords, and literals must be separated with white space. Other tokens should be separated by white space to make the source code more readable. White space includes blanks, horizontal and vertical tabs, new lines, form feeds, and comments.

Keywords

Keywords are identifiers reserved by the language for special use. Although you can use them for preprocessor macro names, it is considered poor programming style. Only the exact spelling of keywords is reserved. For example, auto is reserved but AUTO is not.

Table 4. C and C++ keywords

<table>
<thead>
<tr>
<th>auto</th>
<th>double</th>
<th>int</th>
<th>struct</th>
</tr>
</thead>
<tbody>
<tr>
<td>break</td>
<td>else</td>
<td>long</td>
<td>switch</td>
</tr>
<tr>
<td>case</td>
<td>enum</td>
<td>register</td>
<td>typedef</td>
</tr>
<tr>
<td>char</td>
<td>extern</td>
<td>return</td>
<td>union</td>
</tr>
<tr>
<td>const</td>
<td>float</td>
<td>short</td>
<td>unsigned</td>
</tr>
<tr>
<td>continue</td>
<td>for</td>
<td>signed</td>
<td>void</td>
</tr>
<tr>
<td>default</td>
<td>goto</td>
<td>sizeof</td>
<td>volatile</td>
</tr>
<tr>
<td>do</td>
<td>if</td>
<td>static</td>
<td>while</td>
</tr>
</tbody>
</table>

C++0x

In C++0x, the keyword auto is no longer used as a storage class specifier. Instead, it is used as a type specifier, which can deduce the type of an auto variable from the type of its initializer expression.

The keyword extern was previously used as a storage specifier or as part of a linkage specification. The C++0x standard adds a third usage to use this keyword to specify explicit instantiation declarations.

C

Standard C at the C99 level also reserves the following keywords:
Table 5. C99 keywords

<table>
<thead>
<tr>
<th>_Bool</th>
<th>_Imaginary</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>inline</td>
</tr>
<tr>
<td></td>
<td>restrict</td>
</tr>
</tbody>
</table>

Note:
1. The keyword _Imaginary is reserved for possible future use. For complex number functionality, use _Complex; see Complex literals (C only) for details.
2. The keyword inline is only recognized under compilation with c99 or with the LANG_LVL(STDC99) or LANGLVL(EXTC99) options.
3. The keyword restrict is only recognized under compilation with c99 or with the LANG_LVL(STDC99) or LANGLVL(EXTC99) options.

C++

The C++ language also reserves the following keywords:

Table 6. C++ keywords

<table>
<thead>
<tr>
<th>asm</th>
<th>export</th>
<th>operator</th>
<th>this</th>
</tr>
</thead>
<tbody>
<tr>
<td>bool</td>
<td>false</td>
<td>private</td>
<td>throw</td>
</tr>
<tr>
<td>catch</td>
<td>friend</td>
<td>protected</td>
<td>true</td>
</tr>
<tr>
<td>class</td>
<td>inline</td>
<td>public</td>
<td>try</td>
</tr>
<tr>
<td>const_cast</td>
<td>mutable</td>
<td>reinterpret_cast</td>
<td>typeid</td>
</tr>
<tr>
<td>delete</td>
<td>namespace</td>
<td>static_assert</td>
<td>typename</td>
</tr>
<tr>
<td>dynamic_cast</td>
<td>new</td>
<td>static_cast</td>
<td>using</td>
</tr>
<tr>
<td>dec_type</td>
<td>template</td>
<td>static_cast</td>
<td>virtual</td>
</tr>
<tr>
<td>explicit</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

C++0x
dec_type and static_assert are reserved as keywords only in the C++0x language level.

Keywords for language extensions (IBM extension)

In addition to standard language keywords, z/OS XL C/C++ reserves the following keywords for use in language extensions:

Table 7. Keywords for C and C++ language extensions

<table>
<thead>
<tr>
<th>__asm (C only)</th>
<th><strong>imag</strong> (C only)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>asm</strong> (C only)</td>
<td><strong>inline</strong></td>
</tr>
<tr>
<td><strong>attribute</strong></td>
<td><strong>real</strong> (C only)</td>
</tr>
<tr>
<td><strong>attribute</strong></td>
<td></td>
</tr>
<tr>
<td><strong>complex</strong> (C only)</td>
<td>_static_assert</td>
</tr>
<tr>
<td><strong>const</strong></td>
<td></td>
</tr>
</tbody>
</table>

Note:
1. These keywords are recognized only when the DFP compiler option is in effect.
2. __static_assert is a keyword for C language extension for compatibility with the C++0x standard.

XL C++ reserves the following keywords as language extensions for compatibility with C99.
restrict

z/OS XL C/C++ additionally reserves the following for use as extensions:

<table>
<thead>
<tr>
<th>C</th>
<th>C++</th>
</tr>
</thead>
<tbody>
<tr>
<td>_Packed</td>
<td>__cdecl</td>
</tr>
<tr>
<td>__packed</td>
<td>_Export</td>
</tr>
<tr>
<td>__callback</td>
<td>__ptr32</td>
</tr>
<tr>
<td></td>
<td>__ptr64</td>
</tr>
<tr>
<td></td>
<td>__far1</td>
</tr>
</tbody>
</table>

Note:
1. Recognized only when the METAL compiler option is in effect, which is currently only supported by z/OS XL C.

z/OS XL C/C++ also reserves the following keywords for future use in both C and C++:

| __alignof__ |
| __extension__ |
| __label__ |
| _Pragma |

More detailed information regarding the compilation contexts in which extension keywords are valid is provided in the sections that describe each keyword.

Identifiers

Identifiers provide names for the following language elements:

- Functions
- Objects
- Labels
- Function parameters
- Macros and macro parameters
- Type definitions
- Enumerated types and enumerators
- Structure and union names
- Classes and class members
- Templates
- Template parameters
- Namespaces
An identifier consists of an arbitrary number of letters, digits, or the underscore character in the form:

```
/SM590000/SM590000
```

**Characters in identifiers**

The first character in an identifier must be a letter or the underscore character; however, beginning identifiers with an underscore is considered poor programming style.

The compiler distinguishes between uppercase and lowercase letters in identifiers. For example, PROFIT and profit represent different identifiers. If you specify a lowercase a as part of an identifier name, you cannot substitute an uppercase A in its place; you must use the lowercase letter.

**Note:** If the names have external linkage, and you do not specify the LONGNAME compiler option, names are truncated to eight characters and uppercased in the object file. For example, STOCKONHOLD and stockonhold will both refer to the same object. For more information on external name mapping, see “External identifiers (z/OS only).”

The universal character names for letters and digits outside of the basic source character set are allowed in C++ and at the C99 language level.

**External identifiers (z/OS only)**

By default, external names in C object modules, and external names without C++ linkage in C++ object modules, are formatted as follows:

- All characters are converted to uppercase.
- Names longer than 8 characters are truncated to 8 characters.
- Each underscore character is converted to an at sign (@).

For example, if you compile the following C program:

```c
int test_name[4] = {4, 8, 9, 10};
int test_namesum;

int main(void) {
    int i;
    test_namesum = 0;
    for (i = 0; i < 4; i++)
        test_namesum += test_name[i];
    printf("sum is %d\n", test_namesum);
}
```

The C compiler displays the following message:

```
ERROR CCN3244 ./sum.c:2 External name TEST_NAM cannot be redefined.
```

The compiler changes the external names test_namesum and test_name to uppercase and truncates them to 8 characters. If you specify the CHECKOUT compile-time option, the compiler will generate two informational messages to this effect. Because the truncated names are now the same, the compiler produces an error message and terminates the compilation.

To avoid this problem, you can do either of the following:
Map long external names in the source code to 8 or less characters that you specify, by using the 
#pragma map directive. For example:
#pragma map(verylongname,"sname")

Compile with the LONGNAME compiler option, and use the binder to produce a program object in a 
PDSE, or use the prelinker. This allows up to 1024 characters in external names, mixed-case
characters, and preserves the underscore character. For more information on the binder, prelinker, and
LONGNAME compile-time option, see the z/OS XL C/C++ User's Guide.

IBM-provided functions have names that begin with IBM, CEE, and PLI. In order to prevent conflicts
between runtime functions and user-defined names, the compiler changes all static or external variable
names that begin with IBM, CEE, and PLI in your source program to IB$, CE$, and PL$, respectively, in
the object module. If you are using interlanguage calls, avoid using these prefixes altogether. The compiler
of the calling or called language may or may not change these prefixes in the same manner as the z/OS
XL C/C++ compiler does.

To call an external program or access an external variable that begins with IBM, CEE, or PLI, use the
#pragma map preprocessor directive. The following is an example of #pragma map that forces an
external name to be IBMENTRY:
#pragma map(ibmentry,"IBMENTRY")

Reserved identifiers

Identifiers with two initial underscores or an initial underscore followed by an uppercase letter are reserved
globally for use by the compiler.

- C Identifiers that begin with a single underscore are reserved as identifiers with file scope in both
  the ordinary and tag namespaces.

- C++ Identifiers that begin with a single underscore are reserved in the global namespace.

Although the names of system calls and library functions are not reserved words if you do not include the
appropriate headers, avoid using them as identifiers. Duplication of a predefined name can lead to
confusion for the maintainers of your code and can cause errors at link time or run time. If you include a
library in a program, be aware of the function names in that library to avoid name duplications. You should
always include the appropriate headers when using standard library functions.

The __func__ predefined identifier

The C99 predefined identifier __func__ makes a function name available for use within the function.
Immediately following the opening brace of each function definition, __func__ is implicitly declared by the
compiler. The resulting behavior is as if the following declaration had been made:
static const char __func__[] = "function-name";

where function-name is the name of the lexically-enclosing function. The function name is not mangled.

- C++ The function name is qualified with the enclosing class name or function name. For example, if
  foo is a member function of class X, the predefined identifier of foo is X::foo. If foo is defined within
  the body of main, the predefined identifier of foo is main::X::foo.

- C++ The names of template functions or member functions reflect the instantiated type. For example,
  the predefined identifier for the template function foo instantiated with int, template<classT> void foo()<
is foo<int>.  

Chapter 2. Lexical elements 15
For debugging purposes, you can explicitly use the __func__ identifier to return the name of the function in which it appears. For example:

```c
#include <stdio.h>

void myfunc(void) {
    printf("%s\n", __func__);
    printf("size of __func__ = %d\n", sizeof(__func__));
}

int main() {
    myfunc();
}
```

The output of the program is:

```
myfunc
size of __func__ = 7
```

When the assert macro is used inside a function definition, the macro adds the name of the enclosing function on the standard error stream.

## Literals

The term literal constant, or literal, refers to a value that occurs in a program and cannot be changed. The C language uses the term constant in place of the noun literal. The adjective literal adds to the concept of a constant the notion that we can speak of it only in terms of its value. A literal constant is nonaddressable, which means that its value is stored somewhere in memory, but we have no means of accessing that address.

Every literal has a value and a data type. The value of any literal does not change while the program runs and must be in the range of representable values for its type. The following are the available types of literals:

- "Integer literals"
- "Boolean literals" on page 20
- "Floating-point literals" on page 21
- "Fixed-point decimal literals" on page 23
- "Character literals" on page 24
- "String literals" on page 25

### Integer literals

```c
```
**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

**Integer literals** are numbers that do not have a decimal point or an exponential part. They can be represented as:

- **Decimal integer literals**
- **Hexadecimal integer literals**
- **Octal integer literals**

An integer literal might have a prefix that specifies its base, or a suffix that specifies its type.

**Integer literal syntax**

There are two **long long** features:

- the C99 **long long** feature
- the non-C99 **long long** feature

Both of the two features have the corresponding extension parts:

- the C99 **long long** feature with the associated IBM extensions
- the non-C99 IBM **long long** extension

**Types of integer literals outside of C99 and C++0x**

In the non-C99 modes, you can enable the non-C99 IBM **long long** extension.

When the C99 **long long** feature is not in effect, you can enable the non-C99 IBM **long long** extension.

The following table lists the integer literals and shows the possible data types when the C99 **long long** feature is not enabled.

<table>
<thead>
<tr>
<th>Representation</th>
<th>Suffix</th>
<th>Promotion order</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>int</td>
<td>unsigned int</td>
</tr>
<tr>
<td></td>
<td>long int</td>
<td>unsigned long int</td>
</tr>
<tr>
<td></td>
<td>IBM long long int</td>
<td>IBM unsigned long int</td>
</tr>
</tbody>
</table>
Table 11. Types of integer literals outside of C99 and C++0x (continued)

<table>
<thead>
<tr>
<th>Representation</th>
<th>Suffix</th>
<th>Promotion order</th>
</tr>
</thead>
<tbody>
<tr>
<td>Decimal</td>
<td>None</td>
<td>+</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>None</td>
<td>+ +</td>

<tr>
<td>All</td>
<td>u or U</td>
<td>+</td>
</tr>
<tr>
<td>Decimal</td>
<td>l or L</td>
<td>+</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>l or L</td>
<td>+</td>
</tr>
<tr>
<td>All</td>
<td>Both u or U and l or L</td>
<td>+</td>
</tr>
<tr>
<td>Decimal</td>
<td>ll or LL</td>
<td>+ +</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>ll or LL</td>
<td>+ +</td>
</tr>
<tr>
<td>All</td>
<td>Both u or U and ll or LL</td>
<td>+</td>
</tr>
</tbody>
</table>

Notes:
1. When none of the long long features are enabled, types of integer literals include all the types in this table except the last two columns.
2. IBM The unsigned long int type is not included here in the C++98 and C++03 standards. The C++ compiler includes the type in the implementation for compatibility purposes only.

Types of integer literals in C99 and C++0x

In the C99 modes, the C99 long long feature is enabled automatically.

When the non-C99 IBM long long extension is not in effect, you can enable the C99 long long feature.

After you enable the C99 long long feature, the compiler has all the functionality of the non-C99 IBM long long extension. Aside from literals that are out of range, the only difference is the specific typing rules for decimal integer literals that do not have a suffix containing u or U. Literals that are out of range under the non-C99 IBM long long extension might have implied type long long int or unsigned long long int under the C99 long long feature with the associated IBM extensions.

The following example demonstrates the different behaviors of the compiler when you use these two long long modes:

```c
#include <stdio.h>

int main()
{
    if(0>3999999999-4000000000)
    {
        printf("C99 long long");
    }
    else
    {
        printf("non-C99 IBM long long extension");
    }
}
```

In this example, the values 3999999999 and 4000000000 are too large to fit into the a 32-bit long int type, but they can fit into either the unsigned long or the long long int type. If you enable the C99 long long feature, the two values have the long long int type, so the difference of 3999999999 and 4000000000 is negative. Otherwise, if you enable the non-C99 IBM long long extension, the two values have the unsigned long type, so the difference is positive.
When both the C99 and non-C99 `long long` features are disabled, integer literals that have one of the following suffixes cause a severe compile-time error:

- `l` or `L`
- Both `u` or `U` and `l` or `L`

IBM If a value cannot fit into the `long long` int type, the compiler might use the `unsigned long long` int type for the literal. In this case, the compiler generates a message to indicate that the value is too large.

C++0x IBM To strictly conform to the C++0x standard, the compiler introduces the extended integer safe behavior to ensure that a signed value never becomes an unsigned value after a promotion. After you enable this behavior, if a decimal integer literal that does not have a suffix containing `u` or `U` cannot be represented by the `long long` int type, the compiler issues an error message to indicate that the value of the literal is out of range. The extended integer safe behavior is the only difference between the C99 `long long` feature with the associated IBM extensions and the C99 `long long` feature.

The following table lists the integer literals and shows the possible data types when the C99 `long long` feature is enabled.

<table>
<thead>
<tr>
<th>Representation</th>
<th>Suffix</th>
<th>Promotion order</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td>int</td>
</tr>
<tr>
<td>Decimal</td>
<td>None</td>
<td>+</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>None</td>
<td>+</td>
</tr>
<tr>
<td>All</td>
<td>u or U</td>
<td>+</td>
</tr>
<tr>
<td>Decimal</td>
<td>l or L</td>
<td>+</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>l or L</td>
<td>+</td>
</tr>
<tr>
<td>All</td>
<td>Both u or U and l or L</td>
<td>+</td>
</tr>
<tr>
<td>Decimal</td>
<td>ll or LL</td>
<td>+</td>
</tr>
<tr>
<td>Octal, Hex</td>
<td>ll or LL</td>
<td>+</td>
</tr>
<tr>
<td>All</td>
<td>Both u or U and ll or LL</td>
<td>+</td>
</tr>
</tbody>
</table>

**Note:**

1. The compiler does not support this type if the extended integer safe behavior is enabled.
2. In 32-bit mode, an unsuffixed decimal constant of type `signed long long` is given the type `signed long` in 64-bit mode when the constant is less than `ULLONG_MAX`.

**Decimal integer literals**

A *decimal integer literal* contains any of the digits 0 through 9. The first digit cannot be 0. Integer literals beginning with the digit 0 are interpreted as an octal integer literal rather than as a decimal integer literal.

**Decimal integer literal syntax**

```
digit_1_to_9
```

Chapter 2. Lexical elements 19
The following are examples of decimal literals:
485976
5

A plus (+) or minus (-) symbol can precede a decimal integer literal. The operator is treated as a unary operator rather than as part of the literal. Consider the following example:
-433132211
+20

**Hexadecimal integer literals**

A *hexadecimal integer literal* begins with the 0 digit followed by either an x or X, followed by any combination of the digits 0 through 9 and the letters a through f or A through F. The letters A (or a) through F (or f) represent the values 10 through 15, respectively.

**Hexadecimal integer literal syntax**

```
0x
0X
digit_0_to_f
digit_0_to_F
```

The following are examples of hexadecimal integer literals:
0x3b24
0XF96
0x21
0x3AA
0X29b
0X4bD

**Octal integer literals**

An *octal integer literal* begins with the digit 0 and contains any of the digits 0 through 7.

**Octal integer literal syntax**

```
0
digit_0_to_7
```

The following are examples of octal integer literals:
0
0125
034673
03245

floating-point literals

floating-point literals are numbers that have a decimal point or an exponential part. They can be represented as:

- Real literals
  - Binary floating-point literals
  - Hexadecimal floating-point literals (C only)
- Complex literals

Binary floating-point literals

A real binary floating-point constant consists of the following:

- An integral part
- A decimal point
- A fractional part
- An exponent part
- An optional suffix

Both the integral and fractional parts are made up of decimal digits. You can omit either the integral part or the fractional part, but not both. You can omit either the decimal point or the exponent part, but not both.

Binary floating-point literal syntax

Exponent:

The suffix f or F indicates a type of float, and the suffix l or L indicates a type of long double. If a suffix is not specified, the floating-point constant has a type double.

A plus (+) or minus (-) symbol can precede a floating-point literal. However, it is not part of the literal; it is interpreted as a unary operator.
The following are examples of floating-point literals:

<table>
<thead>
<tr>
<th>floating-point constant</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>5.3876e4</td>
<td>53,876</td>
</tr>
<tr>
<td>4e-11</td>
<td>0.0000000004</td>
</tr>
<tr>
<td>1e+5</td>
<td>100000</td>
</tr>
<tr>
<td>7.321E-3</td>
<td>0.007321</td>
</tr>
<tr>
<td>3.2E+4</td>
<td>32000</td>
</tr>
<tr>
<td>0.5e-6</td>
<td>0.0000005</td>
</tr>
<tr>
<td>0.45</td>
<td>0.45</td>
</tr>
<tr>
<td>6.e10</td>
<td>60000000000</td>
</tr>
</tbody>
</table>

**Hexadecimal floating-point literals (C only)**

Real hexadecimal floating constants, which are a C99 feature, consist of the following:
- a hexadecimal prefix
- a significant part
- a binary exponent part
- an optional suffix

The significant part represents a rational number and is composed of the following:
- a sequence of hexadecimal digits (whole-number part)
- an optional fraction part

The optional fraction part is a period followed by a sequence of hexadecimal digits.

The exponent part indicates the power of 2 to which the significant part is raised, and is an optionally signed decimal integer. The type suffix is optional. The full syntax is as follows:

**Hexadecimal floating-point literal syntax**

The suffix `f` or `F` indicates a type of `float`, and the suffix `l` or `L` indicates a type of `long double`. If a suffix is not specified, the floating-point constant has a type `double`. You can omit either the whole-number part
or the fraction part, but not both. The binary exponent part is required to avoid the ambiguity of the type suffix \( F \) being mistaken for a hexadecimal digit.

**Complex literals**

Complex literals, which are a C99 feature, are constructed in two parts: the real part, and the imaginary part.

**Complex literal syntax**

```
| real part | imaginary part |
```

- **Real part:**
  ```
  floating-point constant
  ```

- **Imaginary part:**
  ```
  floating-point constant + _Complex_I
  ```

The *floating-point constant* can be specified as a decimal or hexadecimal floating-point constant (including optional suffixes), in any of the formats described in the previous sections.

_*Complex_I* is a macro defined in the `complex.h` header file, representing the imaginary unit \( i \), the square root of \( -1 \).

For example, the declaration:

```
varComplex = 2.0f + 2.0f * _Complex_I;
```

initializes the complex variable `varComplex` to a value of \( 2.0 + 2.0i \).

**Related reference**

- "Unary expressions" on page 123
- Complex floating-point types

**Fixed-point decimal literals**

*Fixed-point decimal constants* are a z/OS XL C extension to Standard C. This type is available when you specify the LANGLVL(EXTENDED) compile-time option.

A fixed-point decimal constant has a numeric part and a suffix that specifies its type. The numeric part can include a digit sequence that represents the whole-number part, followed by a decimal point (.), followed by a digit sequence that represents the fraction part. Either the integral part or the fractional part, or both must be present.

A fixed-point constant has the form:
A fixed-point constant has two attributes:
- Number of digits (size)
- Number of decimal places (precision).

The suffix D or d indicates a fixed-point constant.

The following are examples of fixed-point decimal constants:

<table>
<thead>
<tr>
<th>Fixed-point constant</th>
<th>(size, precision)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1234567890123456D</td>
<td>(16, 0)</td>
</tr>
<tr>
<td>12345678.12345678D</td>
<td>(16, 8)</td>
</tr>
<tr>
<td>12345678.d</td>
<td>(8, 0)</td>
</tr>
<tr>
<td>.1234567890d</td>
<td>(10, 10)</td>
</tr>
<tr>
<td>12345.99d</td>
<td>(7, 2)</td>
</tr>
<tr>
<td>000123.990d</td>
<td>(9, 3)</td>
</tr>
<tr>
<td>0.00D</td>
<td>(3, 2)</td>
</tr>
</tbody>
</table>

For more information on fixed-point decimal data types, see z/OS XL C/C++ Programming Guide.

Character literals

A character literal contains a sequence of characters or escape sequences enclosed in single quotation mark symbols, for example 'c'. A character literal may be prefixed with the letter L, for example L'c'. A character literal without the L prefix is an ordinary character literal or a narrow character literal. A character literal with the L prefix is a wide character literal. An ordinary character literal that contains more than one character or escape sequence (excluding single quotes ('), backslashes (\) or new-line characters) is a multicharacter literal.

The type of a narrow character literal is int. The type of a wide character literal is wchar_t. The type of a multicharacter literal is int.

The type of a character literal that contains only one character is char, which is an integral type. The type of a wide character literal is wchar_t. The type of a multicharacter literal is int.

Character literal syntax
At least one character or escape sequence must appear in the character literal, and the character literal must appear on a single logical source line.

The characters can be from the source program character set. You can represent the double quotation mark symbol by itself, but to represent the single quotation mark symbol, you must use the backslash symbol followed by a single quotation mark symbol (\' escape sequence). (See “Escape sequences” on page 31 for a list of other characters that are represented by escape characters.)

Outside of the basic source character set, the universal character names for letters and digits are allowed in C++ and at the C99 language level. In C++, you must compile with the LANGLVL(UCS) option for universal character name support.

The following are examples of character literals:

'\a'
'\\'
L'0'
'\n'

Related reference
“Character types” on page 53
“Source program character set” on page 29
“The Unicode standard” on page 32

String literals

A string literal contains a sequence of characters or escape sequences enclosed in double quotation mark symbols. A string literal with the prefix L is a wide string literal. A string literal without the prefix L is an ordinary or narrow string literal.

In C, the type of narrow string literal is array of char. The type of a wide character string literal is array of wchar_t. Both types have static storage duration.

In C++, the type of a narrow string literal is array of const char. The type of a wide string literal is array of const wchar_t. Both types have static storage duration.

String literal syntax

Multiple spaces contained within a string literal are retained.

Use the escape sequence \n to represent a new-line character as part of the string. Use the escape sequence \\ to represent a backslash character as part of the string. You can represent a single quotation mark symbol either by itself or with the escape sequence \'. You must use the escape sequence \" to represent a double quotation mark.
Outside of the basic source character set, the universal character names for letters and digits are allowed in C++ and at the C99 language level. In C++, you must compile with the LANGLVL(UCS) option for universal character name support.

See the following examples of string literals:

```c
char titles[] = "Handel's "Water Music"";
char *temp_string = "abc" "def" "ghi";  // *temp_string = "abcdefghi\0"
wchar_t *wide_string = L"longstring"
```

This example illustrates escape sequences in string literals:

```c
#include <iostream>
using namespace std;

int main () {
  char *s = "Hi there! \n";
  cout << s;
  char *p = "The backslash character \.";
  cout << p << endl;
  char *q = "The double quotation mark \".\n";
  cout << q;
}
```

This program produces the following output:

```
Hi there! The backslash character \. The double quotation mark ".
```

To continue a string on the next line, use the line continuation character (\ symbol) followed by optional whitespace and a new-line character (required). For example:

```c
char *mail_addr = "Last Name First Name MI Street Address \
  893 City Province Postal code ";
```

In the following example, the string literal second causes a compile-time error.

```c
char *first = "This string continues onto the next\n line, where it ends.";  //compiles successfully.

char *second = "The comment makes the \ invisible to the compiler.";  //compilation error.
```

**Note:** When a string literal appears more than once in the program source, how that string is stored depends on whether strings are read-only or writable. By default, the compiler considers strings to be read-only. z/OS XL C/C++ might allocate only one location for a read-only string; all occurrences refer to that one location. However, that area of storage is potentially write-protected. If strings are writable, then each occurrence of the string has a separate, distinct storage location that is always modifiable. You can use the directive or the ROSTRING compiler option to change the default storage for string literals.

### String concatenation

Another way to continue a string is to have two or more consecutive strings. Adjacent string literals can be concatenated to produce a single string. For example:

```
"hello " "there"  //equivalent to "hello there"
"hello" "there"   //equivalent to "hellothere"
```

Characters in concatenated strings remain distinct. For example, the strings "\xab" and "3" are concatenated to form "\xab3". However, the characters \xab and 3 remain distinct and are not merged to form the hexadecimal character \xab3.

If a wide string literal and a narrow string literal are adjacent, as in the following example:
"hello " L"there"

the result is a wide string literal.

**Note:** In C99, narrow strings can be concatenated with wide string literals. In C++0x, the changes to string literal concatenation in the C99 preprocessor are adopted to provide a common preprocessor interface for C and C++ compilers. Narrow strings can be concatenated with wide string literals in C++0x. For more information, see [C99 preprocessor features adopted in C++0x](#).

Following any concatenation, '\0' of type `char` is appended at the end of each string. For a wide string literal, '\0' of type `wchar_t` is appended. By convention, programs recognize the end of a string by finding the null character. For example:

```c
char *first = "Hello "; //stored as "Hello \0"
char *second = "there"; //stored as "there\0"
char *third = "Hello " "there"; //stored as "Hello there\0"
```

**Related reference**

- "Character types" on page 53
- "Source program character set" on page 29
- "The Unicode standard" on page 32
- String concatenation of u-literals

### Punctuators and operators

A **punctuator** is a token that has syntactic and semantic meaning to the compiler, but the exact significance depends on the context. A punctuator can also be a token that is used in the syntax of the preprocessor.

C99 and C++ define the following tokens as punctuators, operators, or preprocessing tokens:

**Table 13. C and C++ punctuators**

| [] | ( ) | { } | , | : | ; |
| * | = | + | - | += | -= |
| . | -> | ++ | -- | ## |
| & | + | - | ~ | = |
| / | % | < | <= | >= | == |
| ^ | ! | &|& | || |
| *= | /= | %= | += | -= |
| <<= | >>= | &= | ^= | |= |

**C++** In addition to the C99 preprocessing tokens, operators, and punctuators, C++ allows the following tokens as punctuators:

**Table 14. C++ punctuators**

| :: | .* | ->* | new | delete |
| and | and_eq | bitand | bitor | comp |
| not | not_eq | or | or_eq | xor | xor_eq |

### Alternative tokens

Both C and C++ provide the following alternative representations for some operators and punctuators. The alternative representations are also known as **digraphs**.
### Operator or punctuator | Alternative representation
---|---
{ | `<%`
} | `%>`
[ | `<:`
] | `:>`
# | `:%`
## | `:%:%`

**Note:** The recognition of these alternative representations is controlled by the DIGRAPHS option; for more information, see "Digraph characters" on page 33.

In addition to the operators and punctuators listed above, C++ and C at the C99 language level provide the following alternative representations. In C, they are defined as macros in the header file `iso646.h`.

<table>
<thead>
<tr>
<th>Operator or punctuator</th>
<th>Alternative representation</th>
</tr>
</thead>
</table>
&& | and |
| | bitor |
|| | or |
^ | xor |
~ | compl |
& | bitand |
&= | and_eq |
|= | or_eq |
^= | xor_eq |
! | not |
!= | not_eq |
Source program character set

The following lists the basic source character sets that are available at both compile time and run time:

- The uppercase and lowercase letters of the English alphabet:
  
  a b c d e f g h i j k l m n o p q r s t u v w x y z
  A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

- The decimal digits:
  0 1 2 3 4 5 6 7 8 9

- The following graphic characters:
  ! * # % & ( ) + - . / ; < = > ? [ \ ] _ { } ~
  – The caret (^) character in ASCII (bitwise exclusive OR symbol) or the equivalent not (~) character in EBCDIC
  – The split vertical bar (¦) character in ASCII, which may be represented by the vertical bar (|) character on EBCDIC systems.

- The space character

- The control characters representing new-line, horizontal tab, vertical tab, form feed, end of string (NULL character), alert, backspace, and carriage return.

Depending on the compiler option, other specialized identifiers, such as the dollar sign ($) or characters in national character sets, may be allowed to appear in an identifier.

In a source file, a record contains one line of source text; the end of a record indicates the end of a source line.

If you use the #pragma filetag directive to specify the encoding of input files, the compiler converts this encoding to the encoding defined by code page IBM-1047. If you use the LOCALE to specify the encoding for output, the compiler converts the encoding from code page IBM-1047 to the encoding you have specified. These conversions apply to:

- Listings that contain identifier names and source code
- String literals and character constants that are emitted in the object code
- Messages generated by the compiler

They do not apply to source-code annotation in the pseudo-assembly listings.
Therefore, the encoding of the following characters from the basic character set may vary between the source-code generation environment and the runtime environment:

! # [ ] { } ~ ^ |

For a detailed description of the `#pragma filetag` directive and the LOCALE option, refer to the description of internationalization, locales, and character sets in the z/OS XL C/C++ User's Guide.

Related reference
- Characters in identifiers
- “#pragma filetag” on page 433

Multibyte characters

The compiler recognizes and supports the additional characters (the extended character set) which you can meaningfully use in string literals and character constants. The support for extended characters includes multibyte character sets. A multibyte character is a character whose bit representation fits into more than one byte.

z/OS systems represent multibyte characters by using Shiftout <SO> and Shiftin <SI> pairs. Strings are of the form:

```
<SO> x y z <SI>
```

Or they can be mixed:

```
<SO> x <SI> y z <SO> y <SI> z
```

In the above, two bytes represent each character between the <SO> and <SI> pairs. z/OS XL C/C++ restricts multibyte characters to character constants, string constants, and comments.

Multibyte characters can appear in any of the following contexts:

- String literals and character constants. To declare a multibyte literal, use a wide-character representation, prefixed by L. For example:
  ```c
  wchar_t *a = L"wide_char_string";
  wchar_t b = L"wide_char";
  ```
  Strings containing multibyte characters are treated essentially the same way as strings without multibyte characters. Generally, wide characters are permitted anywhere multibyte characters are, but they are incompatible with multibyte characters in the same string because their bit patterns differ. Wherever permitted, you can mix single-byte and multibyte characters in the same string.

- Preprocessor directives. The following preprocessor directives permit multibyte-character constants and string literals:
  - `#define`
  - `#pragma comment`
  - `#include`
  A file name specified in an `#include` directive can contain multibyte characters. For example:
  ```
  #include <multibyte_char/mydir/mysource/multibyte_char.h>
  #include "multibyte_char.h"
  ```

- Macro definitions. Because string literals and character constants can be part of `#define` statements, multibyte characters are also permitted in both object-like and function-like macro definitions.

- The `#` and `##` operators.

- Program comments.

The following are restrictions on the use of multibyte characters:

- Multibyte characters are not permitted in identifiers.
• Hexadecimal values for multibyte characters must be in the range of the code page being used.
• You cannot mix wide characters and multibyte characters in macro definitions. For example, a macro expansion that concatenates a wide string and a multibyte string is not permitted.
• Assignment between wide characters and multibyte characters is not permitted.
• Concatenating wide character strings and multibyte character strings is not permitted.

Character literals
“The Unicode standard” on page 32
“Character types” on page 53

Escape sequences

You can represent any member of the execution character set by an escape sequence. They are primarily used to put nonprintable characters in character and string literals. For example, you can use escape sequences to put such characters as tab, carriage return, and backspace into an output stream.

Escape character syntax

An escape sequence contains a backslash (\) symbol followed by one of the escape sequence characters or an octal or hexadecimal number. A hexadecimal escape sequence contains an x followed by one or more hexadecimal digits (0-9, A-F, a-f). An octal escape sequence uses up to three octal digits (0-7). The value of the hexadecimal or octal number specifies the value of the desired character or wide character.

Note: The line continuation sequence (\ followed by a new-line character) is not an escape sequence. It is used in character strings to indicate that the current line of source code continues on the next line.

The escape sequences and the characters they represent are:

<table>
<thead>
<tr>
<th>Escape sequence</th>
<th>Character represented</th>
</tr>
</thead>
<tbody>
<tr>
<td>\a</td>
<td>Alert (bell, alarm)</td>
</tr>
<tr>
<td>\b</td>
<td>Backspace</td>
</tr>
<tr>
<td>\f</td>
<td>Form feed (new page)</td>
</tr>
<tr>

</tbody>
</table>

The value of an escape sequence represents the member of the character set used at run time. Escape sequences are translated during preprocessing. For example, on a system using the ASCII character codes, the value of the escape sequence \x56 is the letter V. On a system using EBCDIC character codes, the value of the escape sequence \xE5 is the letter V.

Use escape sequences only in character constants or in string literals. An error message is issued if an escape sequence is not recognized.
In string and character sequences, when you want the backslash to represent itself (rather than the beginning of an escape sequence), you must use a  `'\'`  backslash escape sequence. For example:

```cpp
cout << "The escape sequence \n." << endl;
```

This statement results in the following output:

```
The escape sequence \n.
```

## The Unicode standard

The *Unicode Standard* is the specification of an encoding scheme for written characters and text. It is a universal standard that enables consistent encoding of multilingual text and allows text data to be interchanged internationally without conflict. The ISO standards for C and C++ refer to *Information technology – Programming Languages – Universal Multiple-Octet Coded Character Set (UCS), ISO/IEC 10646:2003*. (The term *octet* is used by ISO to refer to a byte.) The ISO/IEC 10646 standard is more restrictive than the Unicode Standard in the number of encoding forms: a character set that conforms to ISO/IEC 10646 is also conformant to the Unicode Standard.

The Unicode Standard specifies a unique numeric value and name for each character and defines three encoding forms for the bit representation of the numeric value. The name/value pair creates an identity for a character. The hexadecimal value representing a character is called a *code point*. The specification also describes overall character properties, such as case, directionality, alphabetic properties, and other semantic information for each character. Modeled on ASCII, the Unicode Standard treats alphabetic characters, ideographic characters, and symbols, and allows implementation-defined character codes in reserved code point ranges. According to the Unicode Standard, the encoding scheme of the standard is therefore sufficiently flexible to handle all known character encoding requirements, including coverage of all the world's historical scripts.

C99 and C++ allow the universal character name construct defined in ISO/IEC 10646 to represent characters outside the basic source character set. Both languages permit universal character names in identifiers, character constants, and string literals. In C++, you must compile with the `LANGLVL(UCS)` option for universal character name support.

The following table shows the generic universal character name construct and how it corresponds to the ISO/IEC 10646 short name.

<table>
<thead>
<tr>
<th>Universal character name</th>
<th>ISO/IEC 10646 short name</th>
</tr>
</thead>
<tbody>
<tr>
<td>where \N is a hexadecimal digit</td>
<td></td>
</tr>
<tr>
<td>\UNNNNNNNNN</td>
<td>NNNNNNNNN</td>
</tr>
<tr>
<td>\uNNNN</td>
<td>0000NNNN</td>
</tr>
</tbody>
</table>

C99 and C++ disallow the hexadecimal values representing characters in the basic character set (base source code set) and the code points reserved by ISO/IEC 10646 for control characters.

The following characters are also disallowed:

- Any character whose short identifier is less than 00A0. The exceptions are 0024 ($), 0040 (@), or 0060 (‘).
- Any character whose short identifier is in the code point range D800 through DFFF inclusive.

### UTF literals (IBM extension)

The ISO C and ISO C++ Committees have approved the implementation of *u-literals* and *U-literals* to support Unicode UTF-16 and UTF-32 character literals, respectively. This introduces new, 16-bit and 32-bit character types, `char16_t` and `char32_t`, as well as a new syntax for specifying UTF-16 and UTF-32...
character and string literals. In C, the newly-introduced types are defined as typedefs inside the `<uchar.h>` header. In C++, the newly-introduced types are separate built-in types.

In C mode, the Unicode literals are enabled under the `EXTENDED` language level, and disabled under the strictly-conforming language levels. When the Unicode literals are enabled, the macro `__IBM_UTF_LITERAL` is predefined to 1, otherwise this macro is not predefined.

In C++ mode, to enable support for UTF literals in your source code, you must compile with the option `LANGLEVEL(EXTENDED0X)`. It can be customized through the option `[NO]KEYWORD(char16_t, char32_t)`. In C++ mode, the Unicode literals and character types are enabled under `EXTENDED` and `EXTENDED0X` language levels, and disabled under other language levels. When the Unicode literals are enabled, the macros `__IBM_UTF_LITERAL` and `__IBMCPP_UTF_LITERAL__` are predefined to 1, otherwise they are not predefined. Under the `EXTENDED` language level, the keywords `char16_t` and `char32_t` are disabled by default (but are available as typedefs via `<uchar.h>`). Under the `EXTENDED0X` language level, these keywords are enabled by default.

The following table shows the syntax for UTF literals.

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>u'character'</td>
<td>Denotes a UTF-16 character.</td>
</tr>
<tr>
<td>u&quot;character-sequence&quot;</td>
<td>Denotes an array of UTF-16 characters.</td>
</tr>
<tr>
<td>U'character'</td>
<td>Denotes a UTF-32 character.</td>
</tr>
<tr>
<td>U&quot;character-sequence&quot;</td>
<td>Denotes an array of UTF-32 characters.</td>
</tr>
</tbody>
</table>

The following example shows how to declare a UTF-16 string and a UTF-32 string:

```c
#include <uchar.h>

char16_t msg16[] = u"From \xbd to \u221e and beyond: \U0010ffff";
char32_t msg32[] = U"From \xbd to \u221e and beyond: \U0010ffff";
```

**String concatenation of u-literals**

The u-literals and U-literals follow the same concatenation rule as wide character literals: the normal character string is widened if they are present. The following shows the allowed combinations. All other combinations are invalid.

<table>
<thead>
<tr>
<th>Combination</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>u&quot;a&quot; u&quot;b&quot;</td>
<td>u&quot;ab&quot;</td>
</tr>
<tr>
<td>u&quot;a&quot; &quot;b&quot;</td>
<td>u&quot;ab&quot;</td>
</tr>
<tr>
<td>&quot;a&quot; u&quot;b&quot;</td>
<td>u&quot;ab&quot;</td>
</tr>
<tr>
<td>U&quot;a&quot; U&quot;b&quot;</td>
<td>U&quot;ab&quot;</td>
</tr>
<tr>
<td>U&quot;a&quot; &quot;b&quot;</td>
<td>U&quot;ab&quot;</td>
</tr>
<tr>
<td>&quot;a&quot; U&quot;b&quot;</td>
<td>U&quot;ab&quot;</td>
</tr>
</tbody>
</table>

Multiple concatenations are allowed, with these rules applied recursively.

**Related reference**

[String concatenation](#)

**Digraph characters**

You can represent unavailable characters in a source program by using a combination of two keystrokes that are called a *digraph character*. The preprocessor reads digraphs as tokens during the preprocessor phase. To enable processing of digraphs, use the DIGRAPH compiler option (which is enabled by default).
The digraph characters are:

\%
<
:>
<%
%>
%:%: or %%%% 

number sign  
left bracket  
right bracket  
left brace  
right brace  
preprocessor macro concatenation operator

You can create digraphs by using macro concatenation. z/OS XL C/C++ does not replace digraphs in string literals or in character literals. For example:

```c
char *s = "<%%>; // stays "<%%>"
```

```c
switch (c) {
    case '<%':{/ *. . .* /} // stays '<%'
    case '%>':{/ *. . .* /} // stays '%>'
}
```

### Trigraph sequences

Some characters from the C and C++ character set are not available in all environments. You can enter these characters into a C or C++ source program using a sequence of three characters called a trigraph. The trigraph sequences are:

<table>
<thead>
<tr>
<th>Trigraph</th>
<th>Single character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>??=</td>
<td>#</td>
<td>pound sign</td>
</tr>
<tr>
<td>??(</td>
<td>[</td>
<td>left bracket</td>
</tr>
<tr>
<td>??)</td>
<td>]</td>
<td>right bracket</td>
</tr>
<tr>
<td>??&lt;</td>
<td>{</td>
<td>left brace</td>
</tr>
<tr>
<td>??&gt;</td>
<td>}</td>
<td>right brace</td>
</tr>
<tr>
<td>?/&gt;</td>
<td>\</td>
<td>backslash</td>
</tr>
<tr>
<td>??'</td>
<td>^</td>
<td>caret</td>
</tr>
<tr>
<td>??!</td>
<td>!</td>
<td>vertical bar</td>
</tr>
<tr>
<td>??-</td>
<td>~</td>
<td>tilde</td>
</tr>
</tbody>
</table>

The preprocessor replaces trigraph sequences with the corresponding single-character representation. For example,

```c
some_array??(i??) = n;
```

Represents:

```c
some_array[i] = n;
```

At compile time, the compiler translates the trigraphs found in string literals and character constants into the appropriate characters they represent. These characters are in the coded character set you select by using the LOCALE compiler option. If you do not specify the LOCALE option, the preprocessor uses code page IBM-1047.

The z/OS XL C/C++ compiler will compile source files that were edited using different encoding of character sets. However, they might not compile cleanly. z/OS XL C/C++ does not compile source files that you edit with the following:

- A character set that does not support all the characters that are specified above, even if the compiler can access those characters by a trigraph.
- A character set for which no one-to-one mapping exists between it and the character set above.
Comments

A comment is text replaced during preprocessing by a single space character; the compiler therefore ignores all comments.

There are two kinds of comments:

- The /* (slash, asterisk) characters, followed by any sequence of characters (including new lines), followed by the */ characters. This kind of comment is commonly called a C-style comment.
- The // (two slashes) characters followed by any sequence of characters. A new line not immediately preceded by a backslash terminates this form of comment. This kind of comment is commonly called a single-line comment or a C++ comment. A C++ comment can span more than one physical source line if it is joined into one logical source line with line-continuation (\) characters. The backslash character can also be represented by a trigraph.

To enable C++ comments in C, you must compile with c99, or with the SSCOMM or LANGLVL(STDC99) or LANGLVL(EXTC99) options.

You can put comments anywhere the language allows white space. You cannot nest C-style comments inside other C-style comments. Each comment ends at the first occurrence of */.

You can also include multibyte characters.

Note: The /* or */ characters found in a character constant or string literal do not start or end comments.

In the following program, the second printf() is a comment:

```c
#include <stdio.h>

int main(void)
{
    printf("This program has a comment.\n");
    /* printf("This is a comment line and will not print.\n"); */
    return 0;
}
```

Because the second printf() is equivalent to a space, the output of this program is:

This program has a comment.

Because the comment delimiters are inside a string literal, printf() in the following program is not a comment.

```c
#include <stdio.h>

int main(void)
{
    printf("This program does not have \n /* NOT A COMMENT */ a comment.\n");
    return 0;
}
```

The output of the program is:

This program does not have
/* NOT A COMMENT */ a comment.

In the following example, the comments are highlighted:
/* A program with nested comments. */

#include <stdio.h>

int main(void)
{
    test_function();
    return 0;
}

int test_function(void)
{
    int number;
    char letter;
    /*
    number = 55;
    letter = 'A';
    /* number = 44; */
    */
    return 999;
}

In test_function, the compiler reads the first /* through to the first */. The second */ causes an error. To avoid commenting over comments already in the source code, you should use conditional compilation preprocessor directives to cause the compiler to bypass sections of a program. For example, instead of commenting out the above statements, change the source code in the following way:

/* A program with conditional compilation to avoid nested comments. */

#define TEST_FUNCTION 0
#include <stdio.h>

int main(void)
{
    test_function();
    return 0;
}

int test_function(void)
{
    int number;
    char letter;
    #if TEST_FUNCTION
    number = 55;
    letter = 'A';
    /*number = 44; */
    #endif /*TEST_FUNCTION */
}

You can nest single line comments within C-style comments. For example, the following program will not output anything:

#include <stdio.h>

int main(void)
{
    /*
    printf("This line will not print.\n");
    // This is a single line comment
    // This is another single line comment
    printf("This line will also not print.\n");
    */
    return 0;
}

Note: You can also use the #pragma comment directive to place comments into an object module.

Chapter 3. Data objects and declarations

The topics in this section discuss the various elements that constitute a declaration of a data object.

Topics are sequenced to loosely follow the order in which elements appear in a declaration. The discussion of the additional elements of data declarations is also continued in Chapter 4, “Declarators,” on page 83.

Overview of data objects and declarations

The following sections introduce some fundamental concepts regarding data objects and data declarations that will be used throughout this reference.

Overview of data objects

A data object is a region of storage that contains a value or group of values. Each value can be accessed using its identifier or a more complex expression that refers to the object. In addition, each object has a unique data type. The data type of an object determines the storage allocation for that object and the interpretation of the values during subsequent access. It is also used in any type checking operations. Both the identifier and data type of an object are established in the object declaration.

An instance of a class type is commonly called a class object. The individual class members are also called objects.

Data types are often grouped into type categories that overlap, such as:

**Fundamental types versus derived types**

Fundamental data types are also known as "basic", "fundamental" or "built-in" to the language. These include integers, floating-point numbers, and characters. Derived types, also known as "compound" types in Standard C++, are created from the set of basic types, and include arrays, pointers, structures, unions, enumerations. All C++ classes are considered compound types.

**Built-in types versus user-defined types**

Built-in data types include all of the fundamental types, plus types that refer to the addresses of basic types, such as arrays and pointers. User-defined types are created by the user from the set of basic types, in typedef, structure, union, and enumeration definitions. C++ classes are considered user-defined types.

**Scalar types versus aggregate types**

Scalar types represent a single data value, while aggregate types represent multiple values, of the same type or of different types. Scalars include the arithmetic types and pointers. Aggregate types include arrays, structures. C++ classes are considered aggregate types.

The following matrix lists the supported data types and their classification into fundamental, derived, scalar, and aggregate types.

</tr>
</tbody>
</table>

Note:

1. Although complex floating-point types are represented internally as an array of two elements, they behave in the same way as real floating-pointing types in terms of alignment and arithmetic operations, and can therefore be considered scalar types.

2. The void type is really an incomplete type, as discussed in "Incomplete types." Nevertheless, Standard C++ defines it as a fundamental type.

3. The C standard does not classify enumerations as either scalar or aggregate. Standard C++ classifies enumerations as scalars.

Incomplete types

The following are incomplete types:

- The void type
- Arrays of unknown size
- Arrays of elements that are of incomplete type
- Structure, union, or enumerations that have no definition
- Pointers to class types that are declared but not defined
- Classes that are declared but not defined

However, if an array size is specified by [ ], indicating a variable length array, the size is considered as having been specified, and the array type is then considered a complete type. For more information, see "Variable length arrays" on page 91.

The following examples illustrate incomplete types:

```c
void *incomplete_ptr;
struct dimension linear; /* no previous definition of dimension */
```

Compatible and composite types

In C, compatible types are defined as:

- two types that can be used together without modification (as in an assignment expression)
- two types that can be substituted one for the other without modification
When two compatible types are combined, the result is a composite type. Determining the resultant composite type for two compatible types is similar to following the usual binary conversions of integral types when they are combined with some arithmetic operators.

Obviously, two types that are identical are compatible; their composite type is the same type. Less obvious are the rules governing type compatibility of non-identical types, user-defined types, type-qualified types, and so on. [Type specifiers on page 49](#) discusses compatibility for basic and user-defined types in C.

---

A separate notion of type compatibility as distinct from being of the same type does not exist in C++. Generally speaking, type checking in C++ is stricter than in C: identical types are required in situations where C would only require compatible types.

**Overview of data declarations and definitions**

A declaration establishes the names and characteristics of data objects used in a program. A definition allocates storage for data objects, and associates an identifier with that object. When you declare or define a type, no storage is allocated.

The following table shows examples of declarations and definitions. The identifiers declared in the first column do not allocate storage; they refer to a corresponding definition. The identifiers declared in the second column allocate storage; they are both declarations and definitions.

<table>
<thead>
<tr>
<th>Declarations</th>
<th>Declarations and definitions</th>
</tr>
</thead>
<tbody>
<tr>
<td>extern double pi;</td>
<td>double pi = 3.14159265;</td>
</tr>
<tr>
<td>struct payroll;</td>
<td>struct payroll {</td>
</tr>
<tr>
<td></td>
<td>char *name;</td>
</tr>
<tr>
<td></td>
<td>float salary;</td>
</tr>
<tr>
<td></td>
<td>} employee;</td>
</tr>
</tbody>
</table>

**Note:**

- The C99 standard no longer requires that all declarations appear at the beginning of a function before the first statement.
- As in C++, you can mix declarations with other statements in your code.

Declarations determine the following properties of data objects and their identifiers:

- Scope, which describes the region of program text in which an identifier can be used to access its object
- Visibility, which describes the region of program text from which legal access can be made to the identifier's object
- Duration, which defines the period during which the identifiers have real, physical objects allocated in memory
- Linkage, which describes the correct association of an identifier to one particular object
• Type, which determines how much memory is allocated to an object and how the bit patterns found in the storage allocation of that object should be interpreted by the program.

The elements of a declaration for a data object are as follows:

- "Storage class specifiers" on page 44, which specify storage duration and linkage
- "Type specifiers" on page 49, which specify data types
- "Type qualifiers" on page 74, which specify the mutability of data values
- Declarators, which introduce and include identifiers
- "Initializers" on page 93, which initialize storage with initial values

In addition, for compatibility with GCC, z/OS XL C/C++ allows you to use attributes to modify the properties of data objects. They are described in "Variable attributes (IBM extension)" on page 105.

All declarations have the form:

Data declaration syntax

```
storage_classSpecifier type_qualifier typeSpec { declarator initializer } ;
```

Tentative definitions

A tentative definition is any external data declaration that has no storage class specifier and no initializer. A tentative definition becomes a full definition if the end of the translation unit is reached and no definition has appeared with an initializer for the identifier. In this situation, the compiler reserves uninitialized space for the object defined.

The following statements show normal definitions and tentative definitions.

```
int i1 = 10;  // definition, external linkage */
static int i2 = 20;  // definition, internal linkage */
extern int i3 = 30;  // definition, external linkage */
int i4;        // tentative definition, external linkage */
static int i5;  // tentative definition, internal linkage */

int i1;        // valid tentative definition */
int i2;        // not legal, linkage disagreement with previous */
int i3;        // valid tentative definition */
int i4;        // valid tentative definition */
int i5;        // not legal, linkage disagreement with previous */
```

C++ does not support the concept of a tentative definition: an external data declaration without a storage class specifier is always a definition.

“Function declarations and definitions” on page 185

---

**static_assert declaration (C++0x)**

In C++0x, static assertions can be declared to detect and diagnose common usage errors at compile time.

A static_assert declaration takes the following form:

```
static_assert declaration syntax
\[\text{static_assert}((\text{constant-expression}, \text{string-literal}))\];
```

The constant-expression must be a constant expression that can be contextually converted to `bool`. If the value of the expression converted in such a way is false, the compiler issues a severe error containing the string literal with the source location of the static_assert declaration. Otherwise, the static_assert declaration has no effect.

You can declare static assertions anywhere that you use a using declaration, including namespace scope, block scope, and class member declaration lists.

The declaration of static assertions does not declare a new type or object, and does not imply any size or time cost at run time.

The C++ programming language also supports the _Static_assert keyword in all language levels for improved compatibility with the C programming language.

The addition of static assertions to the C/C++ language has the following benefits:

- Libraries can detect common usage errors at compile time.
- Implementations of the C/C++ Standard Library can detect and diagnose common usage errors, improving usability.

You can declare static assertions to check important program invariants at compile time.

**Examples: static_assert declaration**

The following example illustrates the use of a static_assert declaration in namespace scope.

```c++
static_assert(sizeof(long) >= 8, "64-bit code generation not enabled/supported.");
```

The following example demonstrates the use of a static_assert declaration in class scope, with templates.

```c++
#include <type_traits>
#include <string>

template<typename T>
struct X {
    static_assert(std::tr1::is_pod<T>::value, "POD required to instantiate class template X.");
    // ...
};

int main() {
    X<std::string> x;
}
```
The following example demonstrates the use of a `static_assert` declaration in block scope, with templates:

```cpp
template< typename T, int N>
void f() {
    static_assert (N >=0, "length of array a is negative.");
    T a[N];
    // ...
}
int main() {
    f<int, -1>();
}
```

The following example shows the use of a `static_assert` declaration with an invalid constant expression.

```cpp
static_assert(1 / 0, "never shows up!");
```

When you compile this program, the compiler does not show the `string literal` in the `static_assert` declaration. Instead, the compiler issues an `error` message indicating that the divisor cannot be zero.

### Storage class specifiers

A storage class specifier is used to refine the declaration of a variable, a function, and parameters. Storage classes determine whether:

- The object has internal, external, or no linkage
- The object is to be stored in memory or in a register, if available
- The object receives the default initial value of 0 or an indeterminate default initial value
- The object can be referenced throughout a program or only within the function, block, or source file where the variable is defined
- The storage duration for the object is maintained throughout program run time or only during the execution of the block where the object is defined

For a variable, its default storage duration, scope, and linkage depend on where it is declared: whether inside or outside a block statement or the body of a function. When these defaults are not satisfactory, you can use a storage class specifier to explicitly set its storage class. The storage class specifiers in C and C++ are:

- `auto`
- `static`
- `extern`
- `mutable`
- `register`

In C++0x, the keyword `auto` is no longer used as a storage class specifier. Instead, it is used as a type specifier. The compiler deduces the type of an `auto` variable from the type of its initializer expression. For more information, see "The auto type specifier (C++0x)" on page 67.

The keyword `extern` was previously used as a storage specifier or as part of a linkage specification. The C++0x standard adds a third usage to use this keyword to specify explicit instantiation declarations. For more information, see "Explicit instantiation" on page 345.
The auto storage class specifier

The `auto` storage class specifier lets you explicitly declare a variable with *automatic storage*. The `auto` storage class is the default for variables declared inside a block. A variable `x` that has automatic storage is deleted when the block in which `x` was declared exits.

You can only apply the `auto` storage class specifier to names of variables declared in a block or to names of function parameters. However, these names by default have automatic storage. Therefore the storage class specifier `auto` is usually redundant in a data declaration.

Storage duration of automatic variables

Objects with the `auto` storage class specifier have automatic storage duration. Each time a block is entered, storage for `auto` objects defined in that block is made available. When the block is exited, the objects are no longer available for use. An object declared with no linkage specification and without the `static` storage class specifier has automatic storage duration.

If an `auto` object is defined within a function that is recursively invoked, memory is allocated for the object at each invocation of the block.

Linkage of automatic variables

An `auto` variable has block scope and no linkage.

---

"Function storage class specifiers" on page 189  
"Initializers" on page 93

---

The static storage class specifier

Objects declared with the `static` storage class specifier have *static storage duration*, which means that memory for these objects is allocated when the program begins running and is freed when the program terminates. Static storage duration for a variable is different from file or global scope: a variable can have static duration but local scope.

The keyword `static` is the major mechanism in C to enforce information hiding.

C++ enforces information hiding through the namespace language feature and the access control of classes. The use of the keyword `static` to limit the scope of external variables is deprecated for declaring objects in namespace scope.

The `static` storage class specifier can be applied to the following declarations:

- Data objects
You cannot use the `static` storage class specifier with the following:
- Type declarations
- Function parameters

At the C99 language level, the `static` keyword can be used in the declaration of an array parameter to a function. The `static` keyword indicates that the argument passed into the function is a pointer to an array of at least the specified size. In this way, the compiler is informed that the pointer argument is never null. See the section on "Static array indices in function parameter declarations (C only)" on page 202 for more information.

**Linkage of static variables**

A declaration of an object that contains the `static` storage class specifier and has file scope gives the identifier internal linkage. Each instance of the particular identifier therefore represents the same object within one file only. For example, if a static variable `x` has been declared in function `f`, when the program exits the scope of `f`, `x` is not destroyed:

```c
#include <stdio.h>

int f(void) {
    static int x = 0;
    x++;
    return x;
}

int main(void) {
    int j;
    for (j = 0; j < 5; j++) {
        printf("Value of f(): %d\n", f());
    }
    return 0;
}
```

The following is the output of the above example:

```
Value of f(): 1
Value of f(): 2
Value of f(): 3
Value of f(): 4
Value of f(): 5
```

Because `x` is a static variable, it is not reinitialized to 0 on successive calls to `f`.

**The extern storage class specifier**

The `extern` storage class specifier lets you declare objects that several source files can use. An `extern` declaration makes the described variable usable by the succeeding part of the current source file. This declaration does not replace the definition. The declaration is used to describe the variable that is externally defined.
An `extern` declaration can appear outside a function or at the beginning of a block. If the declaration describes a function or appears outside a function and describes an object with external linkage, the keyword `extern` is optional.

If a declaration for an identifier already exists at file scope, any `extern` declaration of the same identifier found within a block refers to that same object. If no other declaration for the identifier exists at file scope, the identifier has external linkage.

**C++** restricts the use of the `extern` storage class specifier to the names of objects or functions. Using the `extern` specifier with type declarations is illegal. An `extern` declaration cannot appear in class scope.

### Storage duration of external variables

All `extern` objects have static storage duration. Memory is allocated for `extern` objects before the `main` function begins running, and is freed when the program terminates. The scope of the variable depends on the location of the declaration in the program text. If the declaration appears within a block, the variable has block scope; otherwise, it has file scope.

### Linkage of external variables

**C** Like the scope, the linkage of a variable declared `extern` depends on the placement of the declaration in the program text. If the variable declaration appears outside of any function definition and has been declared `static` earlier in the file, the variable has internal linkage; otherwise, it has external linkage in most cases. All object declarations that occur outside a function and that do not contain a storage class specifier declare identifiers with external linkage.

**C++** For objects in the unnamed namespace, the linkage may be external, but the name is unique, and so from the perspective of other translation units, the name effectively has internal linkage.

**Note:** The `extern` keyword was previously used as a storage specifier or as part of a linkage specification. The C++0x standard adds a third usage to use this keyword to specify explicit instantiation declarations. For more information, see “Explicit instantiation” on page 345.

### The mutable storage class specifier (C++ only)

The `mutable` storage class specifier is used only on a class data member to make it modifiable even though the member is part of an object declared as `const`. You cannot use the `mutable` specifier with names declared as static or `const`, or reference members.

In the following example:

```cpp
class A
{
    public:
        A() : x(4), y(5) { };
        mutable int x;
        int y;
};
```

Chapter 3. Data objects and declarations 47
int main()
{
    const A var2;
    var2.x = 345;
    // var2.y = 2345;
}

the compiler would not allow the assignment var2.y = 2345 because var2 has been declared as const. The compiler will allow the assignment var2.x = 345 because A::x has been declared as mutable.

The register storage class specifier

The register storage class specifier indicates to the compiler that the object should be stored in a machine register. The register storage class specifier is typically specified for heavily used variables, such as a loop control variable, in the hopes of enhancing performance by minimizing access time. However, the compiler is not required to honor this request. Because of the limited size and number of registers available on most systems, few variables can actually be put in registers. If the compiler does not allocate a machine register for a register object, the object is treated as having the storage class specifier auto.

An object having the register storage class specifier must be defined within a block or declared as a parameter to a function.

The following restrictions apply to the register storage class specifier:

- You cannot use pointers to reference objects that have the register storage class specifier.
- You cannot use the register storage class specifier when declaring objects in global scope.
- A register does not have an address. Therefore, you cannot apply the address operator (\&) to a register variable.
- You cannot use the register storage class specifier when declaring objects in namespace scope.

Unlike C, C++ lets you take the address of an object with the register storage class. For example:

```
register int i;
int* b = &i;       // valid in C++, but not in C
```

Storage duration of register variables

Objects with the register storage class specifier have automatic storage duration. Each time a block is entered, storage for register objects defined in that block is made available. When the block is exited, the objects are no longer available for use.

If a register object is defined within a function that is recursively invoked, memory is allocated for the variable at each invocation of the block.

Linkage of register variables

Since a register object is treated as the equivalent to an object of the auto storage class, it has no linkage.
Variables in specified registers (C only) (IBM extension)

When the GENASM compiler option is in effect, you can specify that a particular hardware register is dedicated to a global variable by using an `asm register variable` declaration. Global register variables reserve registers throughout the program; stores into the reserved register are never deleted. The register variable must be of type pointer.

**Register variable declaration syntax**

```
asm("register_specifier")
```

The `register_specifier` is a string representing a hardware register. The register name is CPU-specific. The following are valid register names:

- **r0 to r15 or R0 to R15**
  - General purpose registers

The following are the rules of use for register variables:
- Registers can only be reserved for variables of pointer type.
- A global register variable cannot be initialized.
- The register dedicated for a global register variable should not be a volatile register, or the value stored into the global variable might not be preserved across a function call.
- More than one register variable can reserve the same register; however, the two variables become aliases of each other, and this is diagnosed with a warning.
- The same global register variable cannot reserve more than one register.

**Type specifiers**

Type specifiers indicate the type of the object being declared. The following are the available kinds of types:
- Fundamental or built-in types:
  - Arithmetic types
    - Integral types
    - Boolean types
    - Floating-point types
  - z/OS Fixed-point decimal types
  - Character types
  - The void type
- User-defined types

In the C++0x standard, the following type specifiers are introduced:
- The auto type specifier
- The `decltype(expression)` type specifier
Integral types

Integer types fall into the following categories:

- Signed integer types:
  - signed char
  - short int
  - int
  - long int
  - long long int

- Unsigned integer types:
  - unsigned char
  - unsigned short int
  - unsigned int
  - unsigned long int
  - unsigned long long int

*C++*  
/z/OS XL C++ supports the long long data type for language levels other than ANSI by default. You can also control the support for long long using the LONGLONG suboption of LANGLVL. For example, specifying LANGLVL(ANSI, LONGLONG) would add the long long data type to the ISO language level. Refer to the z/OS XL C/C++ User's Guide for information on using the LANGLVL option.

The unsigned prefix indicates that the object is a nonnegative integer. Each unsigned type provides the same size storage as its signed equivalent. For example, int reserves the same storage as unsigned int. Because a signed type reserves a sign bit, an unsigned type can hold a larger positive integer value than the equivalent signed type.

The declarator for a simple integer definition or declaration is an identifier. You can initialize a simple integer definition with an integer constant or with an expression that evaluates to a value that can be assigned to an integer.

*C++*  
When the arguments in overloaded functions and overloaded operators are integer types, two integer types that both come from the same group are not treated as distinct types. For example, you cannot overload an int argument against a signed int argument.

- "Command-line arguments" on page 210

Boolean types

A Boolean variable can be used to hold the integer values 0 or 1, or the literals true or false, which are implicitly promoted to the integers 1 and 0 respectively, whenever an arithmetic value is necessary. The Boolean type is unsigned and has the lowest ranking in its category of standard unsigned integer types; it
may not be further qualified by the specifiers signed, unsigned, short, or long. In simple assignments, if the left operand is a Boolean type, then the right operand must be either an arithmetic type or a pointer.

**C** Boolean type is a C99 feature. To declare a Boolean variable, use the _Bool type specifier.

**C++** To declare a Boolean variable in C++, use the bool type specifier. The result of the equality, relational, and logical operators is of type bool: either of the Boolean constants true or false.

You can use Boolean types to make Boolean logic tests. A Boolean logic test is used to express the results of a logical operation. For example:

```c
_Bool f(int a, int b)
{    return a==b;
}
```

If a and b have the same value, f returns true. If not, f returns false.

- "Boolean conversions" on page 108

**floating-point types**

floating-point type specifiers fall into the following categories:

- "Real floating-point types"
- "Complex floating-point types" on page 52

**Real floating-point types**

Generic, or binary, floating-point types consist of the following:

- float
- double
- long double

The magnitude ranges of the real floating-point types are given in the following table.

*Table 17. Magnitude ranges of real floating-point types*

<table>
<thead>
<tr>
<th>Type</th>
<th>Range</th>
</tr>
</thead>
<tbody>
<tr>
<td>FLOAT(HEX):</td>
<td></td>
</tr>
<tr>
<td>float</td>
<td>5.397605 -79 - 7.237005 -76</td>
</tr>
<tr>
<td>double</td>
<td>5.397605 -79 - 7.237006 -75</td>
</tr>
<tr>
<td>long double</td>
<td>5.397605 -79 - 7.237006 -75</td>
</tr>
<tr>
<td>FLOAT(IEEE):</td>
<td></td>
</tr>
<tr>
<td>float</td>
<td>1.175494 -38 - 3.402823 -38</td>
</tr>
<tr>
<td>double</td>
<td>2.225074 -308 - 1.797693 -308</td>
</tr>
<tr>
<td>long double</td>
<td>3.362103 -4932 - 1.189731 -4932</td>
</tr>
<tr>
<td>DFP:</td>
<td></td>
</tr>
</tbody>
</table>

If a floating-point constant is too large or too small, the result is undefined by the language.
Note that z/OS XL C/C++ supports IEEE binary floating-point variables as well as IBM z/Architecture® hexadecimal floating-point variables. For details on the FLOAT option, see the z/OS XL C/C++ User's Guide.

The declarator for a simple floating-point declaration is an identifier. Initialize a simple floating-point variable with a float constant or with a variable or expression that evaluates to an integer or floating-point number.

**Complex floating-point types**

The complex type specifiers are:

- `float _Complex`
- `double _Complex`
- `long double _Complex`

The representation and alignment requirements of a complex type are the same as an array type containing two elements of the corresponding real type. The real part is equal to the first element; the imaginary part is equal to the second element.

The equality and inequality operators have the same behavior as for real types. None of the relational operators may have a complex type as an operand.

As an extension to C99, complex numbers may also be operands to the unary operators `++` (increment), `--` (decrement), and `~` (bitwise negation).

**Fixed point decimal types (C only)**

Fixed point decimal types are classified as arithmetic types. To declare fixed point decimal variables and initialize them with fixed point decimal constants, you use the type specifier `decimal`. For this type specifier, `decimal` is a macro that is defined in the `decimal.h` header file. Remember to include `decimal.h` if you use fixed point decimals in your program.

**Fixed point decimal syntax**

```
/*--decimal<(-significant_digits,),,precision_digits--)*/
```

The `significant_digits` is a positive integral constant expression. The second argument, `precision_digits` is optional. If you leave it out, the default value is 0. The type specifiers `decimal(n,0)` and `decimal(n)` are type-compatible.

In the type specifier, `significant_digits` and `precision_digits` have a range of allowed values according to the following rules:

1. `precision_digits <= significant_digits`
2. `1 <= significant_digits <= DEC_DIG`
3. \(0 \leq \text{precision\_digits} \leq \text{DEC\_PRECISION}\)

The decimal.h file defines \text{DEC\_DIG} (the maximum number of digits) and \text{DEC\_PRECISION} (the maximum precision). Currently, it uses a maximum of 31 digits for both limits.

The following examples show how to declare a variable as a fixed point decimal data type:

```c
decimal(10,2) x;
decimal(5,0) y;
decimal(5) z;
decimal(18,10) *ptr;
decimal(8,2) arr[100];
```

In the previous example:
- \(x\) can have values between -99999999.99D and +99999999.99D.
- \(y\) and \(z\) can have values between -9999D and +9999D.
- \(ptr\) is a pointer to type decimal(18,10).
- \(arr\) is an array of 100 elements, where each element is of type decimal(8,2).

### Character types

Character types fall into the following categories:
- Narrow character types:
  - char
  - signed char
  - unsigned char
- Wide character type wchar_t

The char specifier is an integral type. The wchar_t type specifier is an integral type that has enough storage to represent a wide character literal. (A wide character literal is a character literal that is prefixed with the letter L, for example L'x')

- **C** A char is a distinct type from signed char and unsigned char, and the three types are not compatible.

- **C++** For the purposes of distinguishing overloaded functions, a C++ char is a distinct type from signed char and unsigned char.

If it does not matter if a char data object is signed or unsigned, you can declare the object as having the data type char. Otherwise, explicitly declare signed char or unsigned char to declare numeric variables that occupy a single byte. When a char (signed or unsigned) is widened to an int, its value is preserved.

By default, char behaves like an unsigned char. To change this default, you can use the CHARS option or the \#pragma chars directive. See "\#pragma chars on page 418 and CHARS in the z/OS XL C/C++ User’s Guide for more information.
The void type

The void data type always represents an empty set of values. The only object that can be declared with the type specifier void is a pointer.

You cannot declare a variable of type void, but you can explicitly convert any expression to type void. The resulting expression can only be used as one of the following:

- An expression statement
- The left operand of a comma expression
- The second or third operand in a conditional expression.

User-defined types

The following are user-defined types:

- Structures and unions
- Enumerations
- Typedef definitions
  - Classes
  - Elaborated type specifiers

C++ classes are discussed in Chapter 11, “Classes (C++ only),” on page 245. Elaborated type specifiers are discussed in “Scope of class names” on page 249.

Structures and unions

A structure contains an ordered group of data objects. Unlike the elements of an array, the data objects within a structure can have varied data types. Each data object in a structure is a member or field.

A union is an object similar to a structure except that all of its members start at the same location in memory. A union variable can represent the value of only one of its members at a time.

In C++, structures and unions are the same as classes except that their members and inheritance are public by default.

You can declare a structure or union type separately from the definition of variables of that type, as described in “Structure and union type definition” on page 55 and “Structure and union variable declarations” on page 60, or you can define a structure or union data type and all variables that have that type in one statement, as described in “Structure and union type and variable definitions in a single statement” on page 60.
Structures and unions are subject to alignment considerations. For information on changing alignment and packing structures, see “The _Packed qualifier (C only)” on page 104 and “#pragma pack” on page 459.

**Structure and union type definition**

A structure or union type definition contains the `struct` or `union` keyword followed by an optional identifier (the structure tag) and a brace-enclosed list of members.

**Structure or union type definition syntax**

```
struct
union

{  
    member_declaration;
}
```

The `tag_identifier` gives a name to the type. If you do not provide a tag name, you must put all variable definitions that refer to the type within the declaration of the type, as described in “Structure and union type and variable definitions in a single statement” on page 60. Similarly, you cannot use a type qualifier with a structure or union definition; type qualifiers placed in front of the `struct` or `union` keyword can only apply to variables that are declared within the type definition.

**Member declarations**

The list of members provides a structure or union data type with a description of the values that can be stored in the structure or union. The definition of a member has the form of a standard variable declaration. The names of member variables must be distinct within a single structure or union, but the same member name may be used in another structure or union type that is defined within the same scope, and may even be the same as a variable, function, or type name.

A structure or union member may be of any type except:

- any variably modified type
- `void` type
- a function
- any incomplete type

Because incomplete types are not allowed as members, a structure or union type may not contain an instance of itself as a member, but is allowed to contain a pointer to an instance of itself. As a special case, the last member of a structure with more than one member may have an incomplete array type, which is called a flexible array member, as described in Flexible array members (C only).

As an extension to Standard C and C++ for compatibility with GNU C, z/OS XL C/C++ also allows zero-extent arrays as members of structures and unions, as described in Zero-extent array members (IBM extension).

A union member cannot be a class object that has a constructor, destructor, or overloaded copy assignment operator, nor can it be of reference type. A union member cannot be declared with the keyword `static`.

A member that does not represent a bit field can be qualified with either of the type qualifiers `volatile` or `const`. The result is an lvalue.

Structure members are assigned to memory addresses in increasing order, with the first component starting at the beginning address of the structure name itself. To allow proper alignment of components, padding bytes may appear between any consecutive members in the structure layout.
The storage allocated for a union is the storage required for the largest member of the union (plus any padding that is required so that the union will end at a natural boundary of its member having the most stringent requirements). All of a union's components are effectively overlaid in memory: each member of a union is allocated storage starting at the beginning of the union, and only one member can occupy the storage at a time.

**Flexible array members**

A flexible array member is an unbounded array that occurs within a structure. It is a C99 feature and can be used to access a variable-length object. A flexible array member is permitted as the last member of a structure, provided that the structure has more than one named member. It is declared with an empty index as follows:

\[
\text{array_identifier}[];
\]

For example, \( b \) is a flexible array member of structure \( f \).

```c
struct f{
    int a;
    int b[];
};
```

Because a flexible array member has an incomplete type, you cannot apply the `sizeof` operator to a flexible array. In this example, the statement `sizeof(f)` returns the same result as `sizeof(f.a)`, which is the size of an integer. The statement `sizeof(f.b)` cannot be used, because \( b \) is a flexible array member that has an incomplete type.

Any structure containing a flexible array member cannot be a member of another structure or an element of an array, for example:

```c
struct f{
    int a;
    int b[];
};
struct f fa[10]; // Error
```

IBM

To be compatible with GNU C, z/OS XL C/C++ extends Standard C and C++, to ease the restrictions on flexible array members and allow the following situations:

- Flexible array members can be declared in any part of a structure, not just as the last member. [C++]
  The type of any member that follows the flexible array member must be compatible with the type of the flexible array member. [C] The type of any member that follows the flexible array member is not required to be compatible with the type of the flexible array member; however, a warning is issued when a flexible array member is followed by members of an incompatible type. The following example demonstrates this:

  ```c
  struct s {
      int a;
      int b[];
      char c; // XL C compiler issues a warning.
      // XL C/C++ compiler issues an error.
  } f;
  ```

- Structures containing flexible array members can be members of other structures.
- Flexible array members can be statically initialized only if either of the following two conditions is true:
  - The flexible array member is the last member of the structure, for example:

    ```c
    struct f {
        int a;
        int b[];
    } f1 = {1,{1,2,3}}; // Fine
    struct a {
        int b;
    }
    ```
int c[];
int d[];
} e = { 1, {1,2}, 3 };  // Error, c is not the last member of structure a.

– Flexible array members are contained in the outermost structure of nested structures. Members of inner structures cannot be statically initialized, for example:
struct b {
  int c;
  int d[];
};

struct c {
  struct b f;
  int g[];
} h = {{1, {1,2}}, {1,2}};  // Error, member d of structure b is
  // in the inner nested structure.

---

**Zero-extent array members (IBM extension)**

Zero-extent arrays are provided for GNU C/C++ compatibility, and can be used to access a variable-length object.

A zero-extent array is an array with an explicit zero specified as its dimension.

array_identifier [0]

For example, b is a zero-extent array member of structure f.

struct f{
  int a;
  int b[0];
};

The sizeof operator can be applied to a zero-extent array, and the value returned is 0. In this example, the statement sizeof(f) returns the same result as sizeof(f.a), which is the size of an integer. The statement sizeof(f.b) returns 0.

A structure containing a zero-extent array can be an element of an array, for example:

struct f{
  int a;
  int b[0];
}; struct f fa[10];  // Fine

A zero-extent array can only be statically initialized with an empty set {}. Otherwise, it must be initialized as a dynamically allocated array. For example:

struct f{
  int a;
  int b[0];
}; struct f f1 = {100, {}};  // Fine
struct f f2 = {100, {1, 2}};  // Error

If a zero-extent array is not initialized, no static zero filling occurs, because a zero-extent array is defined to have no members. The following example demonstrates this:
#include <stdio.h>

struct s {
  int a;
  int b[0];
};
struct t1 {
    struct s f;
    int c[3];
} g1 = {{1},{1,2}};

struct t2 {
    struct s f;
    int c[3];
} g2 = {{1,{}},{1,2}};

int main() {
    printf("%d %d %d %d\n", g1.f.a, g1.f.b[0], g1.f.b[1], g1.f.b[2]);
    printf("%d %d %d %d\n", g2.f.a, g2.f.b[0], g2.f.b[1], g2.f.b[2]);
    return 0;
}

In this example, the two printf statements produce the same output:
1 1 2 0

A zero-extent array can be declared in any part of a structure, not just as the last member. The type of any member following the zero-extent array is not required to be compatible with the type of the zero-extent array; however, a warning is issued when a zero-extent array is followed by members of an incompatible type. For example:

struct s {
    int a;
    int b[0];
    char c;  // XL C and XL C/C++ compilers both issue a warning.
} f;

Bit field members

Both C and C++ allow integer members to be stored into memory spaces smaller than the compiler would ordinarily allow. These space-saving structure members are called bit fields, and their width in bits can be explicitly declared. Bit fields are used in programs that must force a data structure to correspond to a fixed hardware representation and are unlikely to be portable.

Bit field member declaration syntax

\[\text{type specifier} \text{ declarator} : \text{constant expression};\]

The constant_expression is a constant integer expression that indicates the field width in bits. A bit field declaration may not use either of the type qualifiers const or volatile.

C In C99, the allowable data types for a bit field include qualified and unqualified _Bool, signed int, and unsigned int. The default integer type for a bit field is unsigned.

_Bool bit fields cannot have a width greater than 1 bit. Otherwise, an information severity message is issued to indicate this restriction.

C++ A bit field can be any integral type or enumeration type.

The following structure has three bit-field members kingdom, phylum, and genus, occupying 12, 6, and 2 bits respectively:

struct taxonomy {
    int kingdom : 12;
    int phylum : 6;
    int genus : 2;
};
When you assign a value that is out of range to a bit field, the low-order bit pattern is preserved and the appropriate bits are assigned.

The following restrictions apply to bit fields. You cannot:

- Define an array of bit fields
- Take the address of a bit field
- Have a pointer to a bit field
- Have a reference to a bit field

Bit fields are bit packed. They can cross word and byte boundaries. No padding is inserted between two (non-zero length) bit field members. Bit padding can occur after a bit field member if the next member is a zero length bitfield or a non-bit field. Non-bit field members are aligned based on their declared type. For example, the following structure demonstrates the lack of padding between bit field members, and the insertion of padding after a bit field member that precedes a non-bit field member.

```c
struct {
    int larry : 25; // Bit Field: offset 0 bytes and 0 bits.
    int curly : 25; // Bit Field: offset 3 bytes and 1 bit (25 bits).
    int moe;       // non-Bit Field: offset 8 bytes and 0 bits (64 bits)
} stooges;
```

There is no padding between `larry` and `curly`. The bit offset of `curly` would be 25 bits. The member `moe` would be aligned on the next 4 byte boundary, causing 14 bits a padding between `curly` and `moe`.

Bit fields with a length of 0 must be unnamed. Unnamed bit fields cannot be referenced or initialized.

A zero-width bit field causes the next field to be aligned on the next container boundary where the container is the same size as the underlying type of the bit field. The padding to the next container boundary only takes place if the zero-width bit field has the same underlying type as the preceding bit field member. If the types are different, the zero-width bit field has no effect. A `_Packed` structure, which has a bit field of length 0, causes the next field to align on the next byte boundary.

The following example demonstrates padding, and is valid for all implementations. Suppose that an `int` occupies 4 bytes. The example declares the identifier `kitchen` to be of type struct on_off:

```c
struct on_off {
    unsigned light : 1;
    unsigned toaster : 1;
    int count;       /* 4 bytes */
    unsigned ac : 4;
    unsigned : 4;
    unsigned clock : 1;
    unsigned : 0;
    unsigned flag : 1;
} kitchen;
```

The structure `kitchen` contains eight members totalling 16 bytes. The following table describes the storage that each member occupies:

<table>
<thead>
<tr>
<th>Member name</th>
<th>Storage occupied</th>
</tr>
</thead>
<tbody>
<tr>
<td>light</td>
<td>1 bit</td>
</tr>
<tr>
<td>toaster</td>
<td>1 bit</td>
</tr>
<tr>
<td>(padding — 30 bits)</td>
<td>To the next int boundary</td>
</tr>
<tr>
<td>count</td>
<td>The size of an int (4 bytes)</td>
</tr>
<tr>
<td>ac</td>
<td>4 bits</td>
</tr>
<tr>
<td>(unnamed field)</td>
<td>4 bits</td>
</tr>
</tbody>
</table>

Chapter 3. Data objects and declarations  59
Structure and union variable declarations

A structure or union *declaration* has the same form as a definition except the declaration does not have a brace-enclosed list of members. You must declare the structure or union data type before you can define a variable having that type.

Structure or union variable declaration syntax

```
storage_class_specifier
type_qualifier
struct
union
tag_identifier declarator;
```

The *tag_identifier* indicates the previously-defined data type of the structure or union.

The keyword *struct* is optional in structure variable declarations.

You can declare structures or unions having any storage class. The storage class specifier and any type qualifiers for the variable must appear at the beginning of the statement. Structures or unions declared with the *register* storage class specifier are treated as automatic variables.

The following example defines structure type *address*:

```c
struct address {
  int street_no;
  char *street_name;
  char *city;
  char *prov;
  char *postal_code;
};
```

The following examples declare two structure variables of type *address*:

```c
struct address perm_address;
struct address temp_address;
```

Structure and union type and variable definitions in a single statement

You can define a structure (or union) type and a structure (or union) variable in one statement, by putting a declarator and an optional initializer after the variable definition. The following example defines a union data type (not named) and a union variable (named *length*):

```c
union {
  float meters;
  double centimeters;
  long inches;
} length;
```

Note that because this example does not name the data type, *length* is the only variable that can have this data type. Putting an identifier after *struct* or *union* keyword provides a name for the data type and lets you declare additional variables of this data type later in the program.
To specify a storage class specifier for the variable or variables, you must put the storage class specifier at the beginning of the statement. For example:

```c
static struct {
    int street_no;
    char *street_name;
    char *city;
    char *prov;
    char *postal_code;
} perm_address, temp_address;
```

In this case, both `perm_address` and `temp_address` are assigned static storage.

Type qualifiers can be applied to the variable or variables declared in a type definition. Both of the following examples are valid:

```c
volatile struct class1 {
    char descript[20];
    long code;
    short complete;
} file1, file2;
```

```c
struct class1 {
    char descript[20];
    long code;
    short complete;
} volatile file1, file2;
```

In both cases, the structures `file1` and `file2` are qualified as `volatile`.

**Access to structure and union members**

Once structure or union variables have been declared, members are referenced by specifying the variable name with the dot operator (.) or a pointer with the arrow operator (->) and the member name. For example, both of the following:

```c
perm_address.prov = "Ontario";
p_perm_address -> prov = "Ontario";
```

assign the string "Ontario" to the pointer `prov` that is in the structure `perm_address`.

All references to members of structures and unions, including bit fields, must be fully qualified. In the previous example, the fourth field cannot be referenced by `prov` alone, but only by `perm_address.prov`.

**Anonymous unions**

An *anonymous union* is a union without a name. It cannot be followed by a declarator. An anonymous union is not a type; it defines an unnamed object.

z/OS XL C supports anonymous unions only when you use the LANGLVL(COMMONC) or LANGLVL(EXTENDED) compiler option.

The member names of an anonymous union must be distinct from other names within the scope in which the union is declared. You can use member names directly in the union scope without any additional member access syntax.

For example, in the following code fragment, you can access the data members `i` and `cptr` directly because they are in the scope containing the anonymous union. Because `i` and `cptr` are union members and have the same address, you should only use one of them at a time. The assignment to the member `cptr` will change the value of the member `i`. 
void f()
{
    union { int i; char* cptr; };
    /* ... */
    i = 5;
    cptr = "string_in_union";  // overrides the value 5
}

An anonymous union cannot have protected or private members, and it cannot have member functions. A global or namespace anonymous union must be declared with the keyword **static**.

**Enumerations**

An *enumeration* is a data type consisting of a set of named values that represent integral constants, known as *enumeration constants*. An enumeration is also referred to as an *enumerated type* because you must list (enumerate) each of the values in creating a name for each of them. In addition to providing a way of defining and grouping sets of integral constants, enumerations are useful for variables that have a small number of possible values.

You can declare an enumeration type separately from the definition of variables of that type, as described in "Enumeration type definition" and "Enumeration variable declarations" on page 64; or you can define an enumeration data type and all variables that have that type in one statement, as described in "Enumeration type and variable definitions in a single statement" on page 64.

**Enumeration type definition**

An enumeration type definition contains the **enum** keyword followed by an optional identifier (the enumeration tag) and a brace-enclosed list of enumerators. A comma separates each enumerator in the enumerator list. C99 allows a trailing comma between the last enumerator and the closing brace.

**Enumeration definition syntax**

```
enum tag_identifier 
{
    enumerator 
};
```

The *tag_identifier* gives a name to the enumeration type. If you do not provide a tag name, you must put all variable definitions that refer to the enumeration type within the declaration of the type, as described in "Enumeration type and variable definitions in a single statement" on page 64. Similarly, you cannot use a type qualifier with an enumeration definition; type qualifiers placed in front of the **enum** keyword can only apply to variables that are declared within the type definition.
Elaborated type specifier

Elaborated type specifier syntax

```
enum <tag_identifier> x
```

The elaborated type specifier refers to a previously declared enumeration. The `x` is a variable that has the type `tag_identifier`.

The `enum` keyword can be used to refer to scoped or unscoped enumerations during variable declaration or definition. You cannot use `enum class` or `enum struct` in the elaborated type specifier. For example:

```c
enum class color { red, white, black, yellow };
enum color pic1 = color :: red; // valid
```

Valid, the keyword "enum" is optional in an elaborated type specifier.

```c
color pic2 = color :: white;
```

// Invalid, "enum class" or "enum struct" cannot be used in an elaborated // type specifier.

```c
enum class color pic3 = color :: black;
```

Enumeration members

The list of enumeration members, or enumerators, provides the data type with a set of values.}

```
identifier = enumeration_constant
```

**C** In C, an enumeration constant is of type `int`. If a constant expression is used as an initializer, the value of the expression cannot exceed the range of `int` (that is, `INT_MIN` to `INT_MAX` as defined in the header `limits.h`). Otherwise, the condition is tolerated, a diagnostic message is issued, but the value of the enumeration constant is undefined.

**C++** In C++, each enumeration constant has a value that can be promoted to a signed or unsigned integer value and a distinct type that does not have to be integral. You can use an enumeration constant anywhere an integer constant is allowed, or anywhere a value of the enumeration type is allowed.

The value of an enumeration constant is determined in the following way:

1. An equal sign (`=`) and a constant expression after the enumeration constant gives an explicit value to the enumeration constant. The enumeration constant represents the value of the constant expression.
2. If no explicit value is assigned to the first enumerator, then it takes the value 0 (zero).
3. Enumeration constants with no explicitly assigned values receive the integer value that is one greater than the value represented by the previous enumeration constant.

The following data type declarations list oats, wheat, barley, corn, and rice as enumeration constants. The number under each constant shows the integer value.

```c
enum grain { oats, wheat, barley, corn, rice };
    /* 0 1 2 3 4 */
enum grain { oats=1, wheat, barley, corn, rice };
    /* 1 2 3 4 5 */
enum grain { oats=10, barley, corn=20, rice };
    /* 0 10 11 20 21 */
```
It is possible to associate the same integer with two different enumeration constants. For example, the following definition is valid. The identifiers `suspend` and `hold` have the same integer value.

```c
enum status { run, clear=5, suspend, resume, hold=6 };
/* 0 5 6 7 6 */
```

Each enumeration constant must be unique within the scope in which the enumeration is defined. In the following example, the second declarations of `average` and `poor` cause compiler errors:

```c
func()
{
    enum score { poor, average, good };
    enum rating { below, average, above };
    int poor;
}
```

### Enumeration variable declarations

You must declare the enumeration data type before you can define a variable having that type.

#### Enumeration variable declaration syntax

```
storage_class_specifier
enum tag_identifier declarator
```

The `tag_identifier` indicates the previously-defined data type of the enumeration.

**C++** The keyword `enum` is optional in enumeration variable declarations.

### Enumeration type and variable definitions in a single statement

You can define a type and a variable in one statement by using a declarator and an optional initializer after the variable definition. To specify a storage class specifier for the variable, you must put the storage class specifier at the beginning of the declaration. For example:

```c
register enum score { poor=1, average, good } rating = good;
```

**C++** C++ also lets you put the storage class immediately before the declarator list. For example:

```c
enum score { poor=1, average, good } register rating = good;
```

Either of these examples is equivalent to the following two declarations:

```c
enum score { poor=1, average, good };
register enum score rating = good;
```

Both examples define the enumeration data type `score` and the variable `rating`. `rating` has the storage class specifier `register`, the data type `enum score`, and the initial value `good`.

Combining a data type definition with the definitions of all variables having that data type lets you leave the data type unnamed. For example:

```c
enum { Sunday, Monday, Tuesday, Wednesday, Thursday, Friday,
       Saturday } weekday;
```

defines the variable `weekday`, which can be assigned any of the specified enumeration constants. However, you cannot declare any additional enumeration variables using this set of enumeration constants.
Compatibility of structures, unions, and enumerations (C only)

Within a single source file, each structure or union definition creates a new type that is neither the same as nor compatible with any other structure or union type. However, a type specifier that is a reference to a previously defined structure or union type is the same type. The tag associates the reference with the definition, and effectively acts as the type name. To illustrate this, only the types of structures j and k are compatible in this example:

```c
struct { int a; int b; } h;
struct { int a; int b; } i;
struct S { int a; int b; } j;
struct S k;
```

Compatible structures may be assigned to each other.

Structures or unions with identical members but different tags are not compatible and cannot be assigned to each other. Structures and unions with identical members but using different alignments are not also compatible and cannot be assigned to each other.

You cannot perform comparisons between packed and nonpacked structures or unions of the same type. You cannot assign packed and nonpacked structures or unions to each other, regardless of their type. You cannot pass a packed structure or union argument to a function that expects a nonpacked structure or union of the same type and vice versa.

Since the compiler treats enumeration variables and constants as integer types, you can freely mix the values of different enumerated types, regardless of type compatibility. Compatibility between an enumerated type and the integer type that represents it is controlled by compiler options and related pragmas. For a discussion of the ENUMSIZE compiler option, see the z/OS XL C/C++ User's Guide. For a discussion of the #pragma enum directive, see "#pragma enum" on page 427.

Compatibility across separate source files

When the definitions for two structures, unions, or enumerations are defined in separate source files, each file can theoretically contain a different definition for an object of that type with the same name. The two declarations must be compatible, or the run time behavior of the program is undefined. Therefore, the compatibility rules are more restrictive and specific than those for compatibility within the same source file. For structure, union, and enumeration types defined in separately compiled files, the composite type is the type in the current source file.

The requirements for compatibility between two structure, union, or enumerated types declared in separate source files are as follows:

- If one is declared with a tag, the other must also be declared with the same tag.
- If both are completed types, their members must correspond exactly in number, be declared with compatible types, and have matching names.

For enumerations, corresponding members must also have the same values.

For structures and unions, the following additional requirements must be met for type compatibility:

- Corresponding members must be declared in the same order (applies to structures only).
Corresponding bit fields must have the same widths.

typedef definitions

A typedef declaration lets you define your own identifiers that can be used in place of type specifiers such as int, float, and double. A typedef declaration does not reserve storage. The names you define using typedef are not new data types, but synonyms for the data types or combinations of data types they represent.

The name space for a typedef name is the same as other identifiers. When an object is defined using a typedef identifier, the properties of the defined object are exactly the same as if the object were defined by explicitly listing the data type associated with the identifier.

Examples of typedef definitions

The following statements define LENGTH as a synonym for int and then use this typedef to declare length, width, and height as integer variables:

typef int LENGTH;
LENGTH length, width, height;

The preceding declarations are equivalent to the following declaration:

int length, width, height;

Similarly, typedef can be used to define a structure, union, or C++ class. For example:

typef struct {
    int scruples;
    int drams;
    int grains;
} WEIGHT;

The structure WEIGHT can then be used in the following declarations:

WEIGHT chicken, cow, horse, whale;

In the following example, the type of yds is "pointer to function with no parameters, returning int".

typef int SCROLL(void);
extern SCROLL *yds;

In the following typedef definitions, the token struct is part of the type name: the type of ex1 is struct a; the type of ex2 is struct b.

typef struct a { char x; } ex1, *ptr1;
typef struct b { char x; } ex2, *ptr2;

Type ex1 is compatible with the type struct a and the type of the object pointed to by ptr1. Type ex1 is not compatible with char, ex2, or struct b.
In C++, a typedef name must be different from any class type name declared within the same scope. If the typedef name is the same as a class type name, it can only be so if that typedef is a synonym of the class name.

A C++ class defined in a typedef definition without being named is given a dummy name. Such a class cannot have constructors or destructors. Consider the following example:

```cpp
typedef class {
    ~Trees();
} Trees;
```

In this example, an unnamed class is defined in a typedef definition. Trees is an alias for the unnamed class, but not the class type name. So you cannot define a destructor ~Trees() for this unnamed class; otherwise, the compiler issues an error.

### Declaring typedef names as friends

In the C++0x standard, the extended friend declarations feature is introduced, with which you can declare typedef names as friends. For more information, see "Extended friend declarations" on page 272.

```cpp
// Declarer friend

The auto type specifier (C++0x)

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

C++0x introduces the keyword auto as a new type specifier. auto acts as a placeholder for a type to be deduced from the initializer expression of a variable. With auto type deduction enabled, you no longer need to specify a type while declaring a variable. Instead, the compiler deduces the type of an auto variable from the type of its initializer expression.

The following examples demonstrate the usage of auto type deduction.

```cpp
auto x = 1;       // x : int
float* p;
auto x = p;       // x : float*
auto y = p;       // y : float*

double f();
auto x = f();     // x : double
const auto& y = foo();  // y : const double&
```
class R;
R* h();
auto* x = h(); // x : R*
auto y = h(); // y : R*

int& g();
auto x = g(); // x : int
const auto& y = g(); // y : const int&
auto z = g(); // error, g() does not return a pointer type

By delegating the task of type deduction to the compiler, auto type deduction increases programming convenience, and potentially eliminates typing errors made by programmers. Auto type deduction also reduces the size and improves the readability of programs.

The following two examples demonstrate the benefits of enabling auto type deduction. The first example does not enable auto type deduction.

```cpp
for (vector<int>::iterator i = vec.begin(); i < vec.end(); i++)
{
    int* a = new int(1);
    //...
}
```

With auto type deduction enabled, the first example can be simplified as follows:

```cpp
for (auto i = vec.begin(); i < vec.end(); i++)
{
    auto a = new auto(1);
    //...
}
```

The following rules and constraints apply to the use of auto as a type specifier in auto type deduction.

- Auto type deduction cannot deduce array types.
  ```cpp
  int x[5];
  auto y[5] = x; // error, x decays to a pointer,
                  // which does not match the array type
  ```

- Auto type deduction cannot deduce cv-qualifier or reference type from the initializer.
  ```cpp
  int f();
  auto& x = f(); // error, cannot bind a non-const reference
                  // to a temporary variable
  int& g();
  auto y = g(); // y is of type int
  auto& z = g(); // z is of type int&
  ```

- Auto type deduction supports multi-variable auto declarations. If the list of declarators contains more than one declarator, the type of each declarator can be deduced independently. If the deduced type is not the same in each deduction, the program is ill-formed.
  ```cpp
  auto x=3, y=1.2, *z=new auto(1); // error y: deduced as double,
                                     // but was previously deduced as int
  ```

- The name of the object that is declared can not be used in its initializer expression.
  ```cpp
  auto x = x++; // error
  ```

- Auto can not be used in function parameters.
  ```cpp
  int func(auto x = 3) // error
  { //...
  }
  ```

**Note:** In C++0x, the keyword auto is no longer used as a storage class specifier.
The decltype(expression) type specifier (C++0x)

Note: C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM’s interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

The decltype(expression) specifier is a type specifier introduced in C++0x. With this type specifier, you can get a type that is based on the resultant type of a possibly type-dependent expression.

dcltype(expression) takes expression as an operand. When you define a variable by using decltype(expression), it can be thought of as being replaced by the compiler with the type or the derived type of expression. Consider the following example:

```c++
int i;
static const decltype(i) j = 4;
```

In this example, decltype(i) is equivalent to the type name int.

General rules for using decltype

When you use decltype(expression) to get a type, the following rules are applicable:

1. If expression is an unparenthesized id-expression or class member, decltype(expression) is the type of the entity named by expression. If there is no such entity, or if expression names a set of overloaded functions, the program is ill formed.

2. Otherwise, if expression is a function call or an invocation of an overloaded operator (parentheses around expression are ignored), decltype(expression) is the return type of the statically chosen function.

3. Otherwise, if expression is an lvalue, decltype(expression) is T&, where T is the type of expression.

4. Otherwise, decltype(expression) is the type of expression.

The following example illustrates how these rules are used:

```c++
const int* bar(){
    return new int[0];
}

struct A{
    double x;
};

template <class T> T tFoo(const T& t){
    return t;
}

bool func(){
    return false;
}

struct Foo{
    template <typename T, typename U>
    static decltype((*(T*)0) * (*(U*)0)) foo(const U& arg1, const T& arg2){
```
    return arg1 * arg2;
};

template <typename T, typename U> struct Bar{
    typedef decltype(*T*0) + *U*0) btype;
    static btype bar(T t, U u);
};

int main(){
    int i = 4;
    const int j = 6;
    const int k = i;
    int a[5];
    int *p;
    decltype(i) var1; // int
    decltype(1) var2; // int
    decltype(2+3) var3; // int(+ operator returns an rvalue)
    decltype(i=1) var4 = i; // int&, because assignment to int
    // returns an lvalue
    decltype((i)) var5 = i; // int&
    decltype(j) var6 = 1; // const int
    decltype(k) var7 = j; // const int&
    decltype("decltype") var10 = "decltype"; // const char(&)[9]
    decltype(a) var8; // int[5]
    decltype(a[3]) var9 = i; // int&[] returns an lvalue
    decltype(*p) var11 = i; // int__(*operator returns an lvalue)
    decltype(tFoo(A())) var12; // int
    decltype(func()) var13; // int
    decltype(func()) var14; // bool, parentheses around f() are ignored
    decltype(func) var15; // bool()
    decltype(&func) var16; // bool(*)()
    decltype(A::x) var17; // double A::*
    decltype(Foo::foo(l, 4u)) var18; // double
    decltype(Bar<float, short>::bar(1,3)) var19; // float

    return 0;
}

In this example, the comment after each decltype statement explains the type of the defined variable.

The following example illustrates an incorrect usage of decltype(expression):

```c
    int func(){
        return 0;
    }
    int func(int a){
        return 0;
    }

    int main(){
        int i = 4;
        // Incorrect usage. func names an overload function
        decltype(func) var1;

        // Correct usage. The overload operation is not ambiguous
        decltype(func(int)) var2;

        return 0;
    }
```

In this example, the compiler issues an error message because it does not know which func function to match.
Rules for using decltype with structure member variables

When you use decltype(expression) to get a type, and expression is an unparenthesized member variable of an object expression (with a . operator) or a pointer expression (with a -> operator), the following rules apply:

- If the object expression or the pointer expression is specified with a constant or volatile qualifier, the type qualifier does not contribute to the result of decltype(expression).

- The lvalueness or rvalueness of the object expression or the pointer expression does not affect whether decltype(expression) is a reference type or not.

Example:

```cpp
struct Foo{
    int x;
};

int main(){
    struct Foo f;
    const struct Foo g = {0};
    volatile struct Foo h = &f;
    struct Foo func();

    decltype(g.x) var1; // int
    decltype(h->x) var2; // int
    decltype(func().x) var3; // int
    return 0;
}
```

In this example, the constant qualifier of the object expression g is not desired in the result of decltype(g.x). Similarly, the volatile qualifier of the pointer expression h is not desired in the result of decltype(h->x). The object expression g and the pointer expression h are lvalues, and the object expression func() is an rvalue, but they do not affect whether the decltype results of their unparenthesized member variables are reference types or not.

If expression declared in decltype(expression) is a parenthesized structure member variable, the constant or volatile type qualifier of the parent object expression or pointer expression of expression contributes to the result of decltype(expression). Similarly, the lvalueness or rvalueness of the object expression or the pointer expression affects the result of decltype(expression).

Example:

```cpp
struct Foo{
    int x;
};

int main(){
    int i = 1;
    struct Foo f;
    const struct Foo g = {0};
    volatile struct Foo h = &f;
    struct Foo func();

    decltype((g.x)) var1 = i; // const int&
    decltype((h->x)) var2 = i; // volatile int&
    decltype((func().x)) var3 = 1; // int
    return 0;
}
```

In this example, the result of decltype((g.x)) inherits the constant qualifier of the object expression g. Similarly, the result of decltype((h->x)) inherits the volatile qualifier of the pointer expression h. The
object expression g and the pointer expression h are lvalues, so `decltype((g.x))` and `decltype((h->x))` are reference types. The object expression func() is an rvalue, so `decltype((func().x))` is a nonreference type.

If you use the built-in operators .* or ->* within a `decltype(expression)`, the constant or volatile type qualifier of the parent object expression or pointer expression of `expression` contributes to the result of `decltype(expression)`, regardless of whether `expression` is a parenthesized or an unparenthesized structure member variable. Similarly, the lvalueness or rvalueness of the object expression or the pointer expression affects the result of `decltype(expression)`.

Example:
```cpp
class Foo{
    int x;
};
int main(){
    int i = 0;
    Foo f;
    const Foo &g = f;
    volatile Foo* h = &f;
    const Foo func();

    decltype(f.*&Foo::x) var1 = i; // int&, f is an lvalue
    decltype(g.*&Foo::x) var2 = i; // const int&, g is an lvalue
    decltype(h->*&Foo::x) var3 = i; // volatile int&, h is an lvalue
    decltype((h->*&Foo::x)) var4 = i; // volatile int&, h is an lvalue
    decltype((func().*&Foo::x)) var5 = 1; // const int, func() is an rvalue
    decltype((func().*&Foo::x)) var6 = 1; // const int, func() is an rvalue
    return 0;
}
```

**Side effects and decltype**

If you use `decltype(expression)` to get a type, additional operations in the `decltype` parenthetical context can be performed, but they do not have side effects outside of the `decltype` context. Consider the following example:
```cpp
int i = 5;
static const decltype(i++) j = 4; // i is still 5
```

The variable `i` is not increased by 1 outside of the `decltype` context.

There are exceptions to this rule. In the following example, because the expression given to `decltype` must be valid, the compiler has to perform a template instantiation:
```cpp
template <int N>
struct Foo{
    static const int n=N;
};
int i;
decltype(Foo<101>::n,i) var = i; // int&
```

In this example, `Foo` template instantiation occurs, even though `var` is only determined by the type of the variable `i`.

**Redundant qualifiers and specifiers with decltype**

Because `decltype(expression)` is considered syntactically to be a type specifier, the following redundant qualifiers or specifiers are ignored:
- constant qualifiers
- volatile qualifiers
• & specifiers

The following example demonstrates this case:

```c
int main(){
    int i = 5;
    int & j = i;
    const int k = 1;
    volatile int m = 1;

    // int&, the redundant & specifier is ignored
    decltype(j)& var1 = i;

    // const int, the redundant const qualifier is ignored
    const decltype(k) var2 = 1;

    // volatile int, the redundant volatile qualifier is ignored
    volatile decltype(m) var3;
    return 0;
}
```

**Note:** The functionality of ignoring the redundant & specifiers in `decltype(expression)` is not supported in the current C++0x standard, but it is implemented in this compiler release.

**Template dependent names and decltype**

Without using the `decltype` feature, when you pass parameters from one function to another function, you might not know the exact types of the results that are passed back. The `decltype` feature provides a mechanism to generalize the return types easily. The following program shows a generic function that performs the multiplication operation on some operands:

```c
struct Math{
    template <typename T>
    static T mult(const T& arg1, const T& arg2){
        return arg1 * arg2;
    }
};
```

If `arg1` and `arg2` are not the same type, the compiler cannot deduce the return type from the arguments. You can use the `decltype` feature to solve this problem, as shown in the following example:

```c
struct Foo{
    template<typename T, typename U>
    static decltype((*(T*)0)*(*(U*)0)) mult(const T& arg1, const U& arg2)
    {
        return arg1 * arg2;
    }
};
```

In this example, the return type of the function is the type of the multiplication result of the two template-dependent function parameters.

**The typeof operator and decltype**

IBM The `decltype` feature is similar to the existing `typeof` feature. One difference between these two features is that `decltype` only accepts an expression as its operand, while `typeof` can also accept a type name. Consider the following example:

```c
__typeof__(int) var1; // okay
declaypef(int) var2; // error
```

In this example, `int` is a type name, so it is invalid as the operand of `decltype`.

**Note:** `__typeof__` is an alternate spelling of `typeof`. 

Chapter 3. Data objects and declarations 73
Compatibility of arithmetic types (C only)

Two arithmetic types are compatible only if they are the same type.

The presence of type specifiers in various combinations for arithmetic types may or may not indicate different types. For example, the type `signed int` is the same as `int`, except when used as the types of bit fields; but `char`, `signed char`, and `unsigned char` are different types.

The presence of a type qualifier changes the type. That is, `const int` is not the same type as `int`, and therefore the two types are not compatible.

Type qualifiers

A type qualifier is used to refine the declaration of a variable, a function, and parameters, by specifying whether:

- The value of an object can be changed
- The value of an object must always be read from memory rather than from a register
- More than one pointer can access a modifiable memory address

z/OS XL C/C++ recognizes the following type qualifiers:

- `const`
- `restrict`
- `volatile`

z/OS XL C/C++ includes the following additional type qualifiers to meet the special needs of the z/OS environment:

- `__callback`
- `__far`
- `__ptr32`
- `__ptr64`

Standard C++ refers to the type qualifiers `const` and `volatile` as `cv-qualifiers`. In both languages, the cv-qualifiers are only meaningful in expressions that are lvalues.

When the `const` and `volatile` keywords are used with pointers, the placement of the qualifier is critical in determining whether it is the pointer itself that is to be qualified, or the object to which the pointer points. For a pointer that you want to qualify as `volatile` or `const`, you must put the keyword between the `*` and the identifier. For example:

```c
int * volatile x;  /* x is a volatile pointer to an int */
int * const y = &z; /* y is a const pointer to the int variable z */
```

For a pointer to a `volatile` or `const` data object, the type specifier and qualifier can be in any order, provided that the qualifier does not follow the `*` operator. For example, for a pointer to a `volatile` data object:

```c
volatile int *x;  /* x is a pointer to a volatile int */
```

or

```c
int volatile *x;  /* x is a pointer to a volatile int */
```
For a pointer to a const data object:

```c
const int * y; /* y is a pointer to a const int */
```

or

```c
int const * y; /* y is a pointer to a const int */
```

The following examples contrast the semantics of these declarations:

<table>
<thead>
<tr>
<th>Declaration</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>const int * ptr1;</code></td>
<td>Defines a pointer to a constant integer: the value pointed to cannot be changed.</td>
</tr>
<tr>
<td><code>int * const ptr2;</code></td>
<td>Defines a constant pointer to an integer: the integer can be changed, but <code>ptr2</code> cannot point to anything else.</td>
</tr>
<tr>
<td><code>const int * const ptr3;</code></td>
<td>Defines a constant pointer to a constant integer: neither the value pointed to nor the pointer itself can be changed.</td>
</tr>
</tbody>
</table>

You can put more than one qualifier on a declaration: the compiler ignores duplicate type qualifiers.

A type qualifier cannot apply to user-defined types, but only to objects created from a user-defined type. Therefore, the following declaration is illegal:

```c
volatile struct omega {
    int limit;
    char code;
} group;
```

However, if a variable or variables are declared within the same definition of the type, a type qualifier can be applied to the variable or variables by placing it at the beginning of the statement or before the variable declarator or declarators. Therefore:

```c
volatile struct omega {
    int limit;
    char code;
} group;
```

provides the same storage as:

```c
struct omega {
    int limit;
    char code;
} volatile group;
```

In both examples, the `volatile` qualifier only applies to the structure variable `group`.

When type qualifiers are applied to a structure, class, or union, or class variable, they also apply to the members of the structure, class or union.

**Related reference**

- “Pointers” on page 86
- “Constant and volatile member functions” on page 258

**The __callback type qualifier**

The keyword `__callback` is a qualifier that can be applied only to a function pointer type. The qualifier instructs the compiler to generate extra code in the call sites to assist the call, and thus allows the function pointer to point to either XPLINK or non-XPLINK functions. Under normal circumstances, a non-XPLINK function pointer is incompatible with XPLINK compilation units.
The keyword can appear in the declarator part of a function pointer declaration, wherever a cv-qualifier can appear. For example,

```c
int (*__callback foo)(int);
```
declares `foo` to be a function pointer that might point to non-XPLINK functions. `foo` will then have fewer restrictions on what it can reference and can thus be used with XPLINK compilation units.

XPLINK and non-XPLINK compilation units cannot be statically bound; the two linkages can be mixed only across DLL boundaries. Moreover, a function pointer that points to a non-XPLINK function cannot be used in XPLINK DLLs unless the pointer is passed across the boundary explicitly as a function argument. The `__callback` qualifier relaxes the latter restriction, at the expense of extra code sequences in the call site.

Semantically, the `__callback` keyword is a language extension that has a single effect: to instruct the compiler to generate assistance code. It does not take part in type definition. The keyword also has no effect on the following:

- Type (such as in overload resolution).
- Name mangling.
- Allocation of the pointer object in memory.

It is the responsibility of the programmer to make sure that the function pointer is appropriately `__callback`-qualified for all call sites that require it.

**The const type qualifier**

The `const` qualifier explicitly declares a data object as something that cannot be changed. Its value is set at initialization. You cannot use `const` data objects in expressions requiring a modifiable lvalue. For example, a `const` data object cannot appear on the left side of an assignment statement.

In C++, all `const` declarations must have initializers, except those referencing externally defined constants. A `const` object can appear in a constant expression if it is an integer and it is initialized to a constant. The following example demonstrates this:

```c
const int k = 10;
int ary[k]; /* allowed in C++, not legal in C */
```

In C++ a global `const` object without an explicit storage class is considered `static` by default, with internal linkage.

```c
const int k = 12; /* Different meanings in C and C++ */
static const int k2 = 120; /* Same meaning in C and C++ */
extern const int k3 = 121; /* Same meaning in C and C++ */
```

Because its linkage is assumed to be internal, a `const` object can be more easily defined in header files in C++ than in C.

In C++, an item can be both `const` and `volatile`. In this case the item cannot be legitimately modified by its own program but can be modified by some asynchronous process.
The __far type qualifier (C only)

When the METAL option is in effect, you can use the __far keyword to qualify a pointer type so that it can access additional data spaces in access-register (AR) mode. The upper half of the pointer contains the access-list-entry token (ALET), which identifies the secondary virtual address space you want to access. The lower half the pointer is the offset within the secondary virtual address space. The size of a __far-qualified pointer is increased to 8 bytes in 31-bit mode and 16 bytes in 64-bit mode. In 31-bit mode, the upper 4 bytes contain the ALET, and the lower 4 bytes is the address within the data space. In 64-bit mode, bytes 0-3 are unused, bytes 4-7 are the ALET, and bytes 8-15 are the address within the data space.

The __far keyword must appear in the declarator part of a pointer declaration, wherever a cv-qualifier can be used. For example,

```c
int * __far p;
```

declares p to be a __far pointer to int.

__far pointers can appear in global scope and function scope, in simple assignment and in implicit assignment via function parameter passing. However, if they are used inside a function in operations that access the data space, such as dereferencing, the function must be in AR mode (that is, with the ARMODE compiler option in effect, or qualified with the armode function attribute).

A normal pointer can be converted to a __far pointer explicitly through typecasting or implicitly through assignment. The ALET of the __far pointer is set to zero. A __far pointer can be explicitly converted to a normal pointer through typecasting; the normal pointer keeps the offset of the __far pointer and the ALET is lost. A __far pointer cannot be implicitly converted to a normal pointer.

Pointer arithmetic is supported for __far pointers, with the ALET part being ignored. If the two ALETS are different, the results may have no meaning.

Two __far pointers can be compared for equality and inequality using the == and != operators. The whole pointer is compared. To compare for equality of the offset only, use the built-in function to extract the offset and then compare. To compare for equality of the ALET only, use the built-in function to extract the ALET and then compare. For more information on the set of built-in functions that operate on __far pointers, see z/OS XL C/C++ Programming Guide.

Two __far pointers can be compared using the >, <, >=, and <= relational operators. The ALET parts of the pointers are ignored in this operation. There is no ordering between two __far pointers if their ALETS are different, and between a NULL pointer and any __far pointers. The result is meaningless if they are compared using relational operators.

When a __far pointer and a normal pointer are involved in an operation, the normal pointer is implicitly converted to __far before the operation. There is unspecified behavior if the ALETS are different. For example:

```c
int * __far p;
int * __far q;
ptrdiff_t chunk;
...

if (p == q) {
    p = p + 1024;
}
```
if (p < q) {
    chunk = q - p;
} else {
    chunk = p - q;
}

The result of the & (address) operator is a normal pointer, except for the following cases:

- If the operand of & is the result of an indirection operator (*), the type of & is the same as the operand of the indirection operator.
- If the operand of & is the result of the arrow operator (->, structure member access), the type of & is the same as the left operand of the arrow operator.

For example:

```c
int * __far p;
int * __far q;
...
q = &(*(p+2)); // result of & is a __far pointer; the ALET is the same as p.
```

```c
struct S {
   int b;
} * __far r;
...
q = & r->b; // result of & is a __far pointer; the ALET is the same as r.
```

For more information on ARMODE and METAL compiler options, see ARMODE and METAL compiler options in the z/OS XL C/C++ User's Guide.

"The armode | noarmode function attribute (C only)" on page 206

The __ptr32 type qualifier

The keyword __ptr32 is a qualifier that can be applied to a pointer type to constrain its size to 32 bits. This language extension is provided to facilitate porting structures with pointer members from 31- to 64-bit mode. The qualifier is accepted and ignored in 31-bit mode.

The size of a pointer type doubles to 64 bits in 64-bit mode. Doubling the size of a pointer changes the layout of a structure that contains pointer members. If the object referenced by a pointer member resides within a 31-bit addressing space, constraining the pointer to 32 bits can reduce some of the unexpected effects of moving to 64-bit mode.

The __ptr32 keyword can appear in the declarator part of a pointer declaration, wherever a cv-qualifier can be used. For example,

```c
int * __ptr32 p;
```

declares p to be a 32-bit pointer to int.

```c
int * __ptr32 *q;
```

declares q to be a 64-bit pointer to a 32-bit pointer to int.

```c
int * __ptr32 const r;
```

declares r to be a const 32-bit pointer.

Pointers with external linkage must be __ptr32-qualified consistently across all compilation units. If a pointer is declared 31-bit in one compilation unit and 64-bit in another, the behavior is undefined.
 Assignment of 32-bit and 64-bit pointers to each other is permitted. The compiler generates an implicit conversion or truncates without emitting a diagnostic.

**Note:** The terms *31-bit mode* and *32-bit mode* are used interchangeably when there is no ambiguity. The term *32-bit mode* is commonly used in the industry to refer to a class of machines, to which z/OS in 31-bit mode belongs. Strictly speaking, *31-bit mode* refers to the addressing mode of the architecture, and *32 bits* refers to the size of the pointer type. In z/OS 31-bit addressing mode, the size of a pointer is four bytes. However, the high-order bit is reserved for system use, and is not used to form the address. The addressing range in this mode is therefore 2 gigabytes. In 64-bit mode, the size of a pointer is eight bytes, and all 64 bits participate in addressing. When a `__ptr32` pointer is dereferenced, a 64-bit address is formed by filling the 33 missing high-order bits with zeros. The program using that address should make sure it is valid within the address space of the application.

**The __ptr64 type qualifier (C only)**

The keyword `__ptr64` is a qualifier that can be applied to a pointer type to constrain its size to 64 bits. When you need to switch addressing mode (AMODE) between programs, this language extension enables the handling of a 64-bit pointer by an AMODE 31 function without dereferencing it, for example, passing it as a parameter or receiving it as a return value.

**Note:** The `__ptr64` qualifier can be used only when the METAL compiler option is specified.

The `__ptr64` keyword can be used only to qualify a pointer type. For example,

```c
int *__ptr64 p; /* 64-bit pointer */
int *r; /* 32-bit pointer, default to the model's size */
int *__ptr64 const q; /* 64-bit const pointer */
int *__far __ptr64 s; /* 64-bit far pointer */
```

For further information on the METAL compiler option, see z/OS XL C/C++ User's Guide. For further information on AMODE switching, see z/OS Metal C Programming Guide and Reference.

**The restrict type qualifier**

A pointer is the address of a location in memory. More than one pointer can access the same chunk of memory and modify it during the course of a program. The restrict (or `__restrict` or `__restrict__`) type qualifier is an indication to the compiler that, if the memory addressed by the restrict-qualified pointer is modified, no other pointer will access that same memory. The compiler may choose to optimize code involving restrict-qualified pointers in a way that might otherwise result in incorrect behavior. It is the responsibility of the programmer to ensure that restrict-qualified pointers are used as they were intended to be used. Otherwise, undefined behavior may result.

If a particular chunk of memory is not modified, it can be aliased through more than one restricted pointer. The following example shows restricted pointers as parameters of `foo()`, and how an unmodified object can be aliased through two restricted pointers.

```c
void foo(int n, int * restrict a, int * restrict b, int * restrict c)
{
    int i;
    for (i = 0; i < n; i++)
        a[i] = b[i] + c[i];
}
```

Assignments between restricted pointers are limited, and no distinction is made between a function call and an equivalent nested block.
In nested blocks containing restricted pointers, only assignments of restricted pointers from outer to inner blocks are allowed. The exception is when the block in which the restricted pointer is declared finishes execution. At that point in the program, the value of the restricted pointer can be carried out of the block in which it was declared.

Notes:

1. The restrict qualifier is represented by the following keywords (all have the same semantics):
   - The restrict keyword is recognized in C, under compilation with c99 or the LANG_LVL(STDC99) or LANG_LVL(EXTC99) options, and in C++ under the LANG_LVL(EXTENDED) or KEYWORD (RESTRICT) options. The __restrict and __restrict__ keywords are recognized in both C, at all language levels, and C++, at LANG_LVL(EXTENDED).

The volatile type qualifier

The volatile qualifier maintains consistency of memory access to data objects. Volatile objects are read from memory each time their value is needed, and written back to memory each time they are changed. The volatile qualifier declares a data object that can have its value changed in ways outside the control or detection of the compiler (such as a variable updated by the system clock or by another program). This prevents the compiler from optimizing code referring to the object by storing the object's value in a register and re-reading it from there, rather than from memory, where it may have changed.

Accessing any lvalue expression that is volatile-qualified produces a side effect. A side effect means that the state of the execution environment changes.

References to an object of type "pointer to volatile" may be optimized, but no optimization can occur to references to the object to which it points. An explicit cast must be used to assign a value of type "pointer to volatile T" to an object of type "pointer to T". The following shows valid uses of volatile objects.

```c
volatile int * pvol;
int *ptr;
pvol = ptr;     /* Legal */
ptr = (int *)pvol; /* Explicit cast required */
```

A signal-handling function may store a value in a variable of type sig_atomic_t, provided that the variable is declared volatile. This is an exception to the rule that a signal-handling function may not access variables with static storage duration.

An item can be both const and volatile. In this case the item cannot be legitimately modified by its own program but can be modified by some asynchronous process.
Type attributes (IBM extension)

Type attributes are language extensions that allow you to use named attributes to specify special properties of user-defined types. Type attributes apply to the definitions of user-defined types, such as structures, unions, enumerations, classes. Any objects that are declared as having that type will have the attribute applied to them.

A type attribute is specified with the keyword `__attribute__` followed by the attribute name and any additional arguments the attribute name requires. Although there are variations, the syntax of a type attribute is of the general form:

```
Type attribute syntax — aggregate types
struct
union
enum
class
__attribute__((tag_identifier(attribute name)))
{member_definition_list};
```

```
Type attribute syntax — typedef declarations
typedef—type_declaration—type_name—__attribute__((attribute name));
```

For unsupported attribute names, the z/OS XL C/C++ compiler issues diagnostics and ignores the attribute specification. Multiple attribute names can be specified in the same attribute specification.

The following type attributes are supported:
- `amode31|amode64` type attributes
- `armode|noarmode` type attribute

Related reference
- “Variable attributes (IBM extension)” on page 105
- “Function attributes (IBM extension)” on page 205

The amode31 | amode64 type attribute (C only)

For use with the METAL compiler option, the `amode31` type attribute allows you to define a `typedef` of a function or function pointer type to operate in addressing mode (AMODE) 31 and the `amode64` type attribute allows you to define a `typedef` of a function or function pointer type to operate in AMODE 64.

```
amode31 | amode64 function attribute syntax
__attribute__((amode31 | amode64))
```

The following example declares a typedef of function pointer `foo` that is in AMODE 64:

```
typedef void (*foo)(int) __attribute__((amode64));
```

For information on the METAL compiler option, see the METAL compiler option description in `z/OS XL C/C++ User's Guide`. For information on AMODE switching, see `z/OS Metal C Programming Guide and Reference`. 
The armode | noarmode type attribute (C only)

For use with the METAL compiler option, the armode type attribute allows you to define a typedef of function or function pointer type as operating in access-register (AR) mode. AR mode allows a C function to access multiple additional data spaces, and manipulate more data in memory.

armode function attribute syntax

\[
\_\_attribute\_\_\_\_\_\_(\text{armode})
\]

Functions in AR mode can call functions not in AR mode, and vice versa.

The following example declares a typedef of function pointer foo that is in AR mode, and then declares bar as a function that passes function pointer foo as a parameter:

```c
typedef void (*foo) (int) __attribute__((armode));
void bar (foo);
```

The attribute overrides the default setting of the ARMODE compiler option for the specified type. Note that this attribute is only supported when the METAL compiler option is in effect.

For more information on ARMODE and METAL compiler options, see ARMODE and METAL compiler options in the z/OS XL C/C++ User's Guide.

Chapter 4. Declarators

This section continues the discussion of data declarations and includes information on type names, pointers, arrays, references, initializers and variable attributes.

Overview of declarators

A declarator designates a data object or function. A declarator can also include an initialization. Declarators appear in most data definitions and declarations and in some type definitions.

For data declarations, a declarator has the form:

Declarator syntax

```
| pointer_operator | direct_declarator | initializer |
```

Direct declarator:

```
declarator_name
direct_declarator
constant_expression
```

Pointer operator (C only):

```
* type_qualifiers
```

Declarator name (C only):

```
identifier
```

Pointer operator (C++ only):

```
$ type_qualifiers
&
:: nested_name_specifier
` type_qualifiers
```

Declarator name (C++ only):

```
identifier_expression
:: nested_name_specifier
` type_name
```

The type_qualifiers represent one or a combination of const and volatile.

A nested_name_specifier is a qualified identifier expression. An identifier_expression can be a qualified or unqualified identifier.

Initializers are discussed in “Initializers” on page 93.
For information on function declarators, see “Function declarators” on page 200.

The following are known as *derived declarator* types, and are therefore discussed in this section:

- “Pointers” on page 86
- “Arrays” on page 90
- “References (C++ only)” on page 92

z/OS XL C/C++ includes two additional qualifiers, which are described in “Declarator qualifiers” on page 104.

IBM In addition, for compatibility with GNU C and C++, z/OS XL C/C++ allows you to use *variable attributes* to modify the properties of data objects. As they are normally specified as part of the declarator in a declaration, they are described in this section, in “Variable attributes (IBM extension)” on page 105.

**Related reference**

“Type qualifiers” on page 74

**Examples of declarators**

The following table indicates the declarators within the declarations:

<table>
<thead>
<tr>
<th>Declaration</th>
<th>Declarator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>int owner;</td>
<td>owner</td>
<td>owner is an integer data object.</td>
</tr>
<tr>
<td>int *node;</td>
<td>*node</td>
<td>node is a pointer to an integer data object.</td>
</tr>
<tr>
<td>int names[126];</td>
<td>names[126]</td>
<td>names is an array of 126 integer elements.</td>
</tr>
<tr>
<td>volatile int min;</td>
<td>min</td>
<td>min is a volatile integer.</td>
</tr>
<tr>
<td>int * volatile volume;</td>
<td>* volatile volume</td>
<td>volume is a volatile pointer to an integer.</td>
</tr>
<tr>
<td>volatile int * next;</td>
<td>*next</td>
<td>next is a pointer to a volatile integer.</td>
</tr>
<tr>
<td>volatile int * sequence[5];</td>
<td>*sequence[5]</td>
<td>sequence is an array of five pointers to volatile integer data objects.</td>
</tr>
<tr>
<td>extern const volatile int clock;</td>
<td>clock</td>
<td>clock is a constant and volatile integer with static storage duration and external linkage.</td>
</tr>
<tr>
<td>int * __far p;</td>
<td>* __far p</td>
<td>p is a __far pointer to an integer.</td>
</tr>
</tbody>
</table>

**Type names**

A *type name*, is required in several contexts as something that you must specify without declaring an object; for example, when writing an explicit cast expression or when applying the `sizeof` operator to a type. Syntactically, the name of a data type is the same as a declaration of a function or object of that type, but without the identifier.

To read or write a type name correctly, put an "imaginary" identifier within the syntax, splitting the type name into simpler components. For example, `int` is a type specifier, and it always appears to the left of the identifier in a declaration. An imaginary identifier is unnecessary in this simple case. However, `int`
*{[5]}* (an array of 5 pointers to `int`) is also the name of a type. The type specifier `int *` always appears to the left of the identifier, and the array subscripting operator always appears to the right. In this case, an imaginary identifier is helpful in distinguishing the type specifier.

As a general rule, the identifier in a declaration always appears to the left of the subscripting and function call operators, and to the right of a type specifier, type qualifier, or indirection operator. Only the subscripting, function call, and indirection operators may appear in a type name declaration. They bind according to normal operator precedence, which is that the indirection operator is of lower precedence than either the subscripting or function call operators, which have equal ranking in the order of precedence. Parentheses may be used to control the binding of the indirection operator.

It is possible to have a type name within a type name. For example, in a function type, the parameter type syntax nests within the function type name. The same rules of thumb still apply, recursively.

The following constructions illustrate applications of the type naming rules.

**Table 18. Type names**

<table>
<thead>
<tr>
<th>Syntax</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>int *{[5]}</code></td>
<td>array of 5 pointers to <code>int</code></td>
</tr>
<tr>
<td><code>int (*{[5]}</code></td>
<td>pointer to an array of 5 integers</td>
</tr>
<tr>
<td><code>int (*{[*]}</code></td>
<td>pointer to an variable length array of an unspecified number of integers</td>
</tr>
<tr>
<td><code>int *()</code></td>
<td>function with no parameter specification returning a pointer to <code>int</code></td>
</tr>
<tr>
<td><code>int (*)(void)</code></td>
<td>function with no parameters returning an <code>int</code></td>
</tr>
<tr>
<td><code>int (*const [])(unsigned int, ...)</code></td>
<td>array of an unspecified number of constant pointers to functions returning an <code>int</code>. Each function takes one parameter of type <code>unsigned int</code> and an unspecified number of other parameters.</td>
</tr>
</tbody>
</table>

The compiler turns any function designator into a pointer to the function. This behavior simplifies the syntax of function calls.

```c
int foo(float);  /* foo is a function designator */
int (*p)(float); /* p is a pointer to a function */
p=&foo;          /* legal, but redundant */
p=foo;           /* legal because the compiler turns foo into a function pointer */
```

In **C++**, the keywords `typename` and `class`, which are interchangeable, indicate the name of the type.
Pointers

A pointer type variable holds the address of a data object or a function. A pointer can refer to an object of any one data type; it cannot refer to a bit field or a reference.

Some common uses for pointers are:

- To access dynamic data structures such as linked lists, trees, and queues.
- To access elements of an array or members of a structure or C++ class.
- To access an array of characters as a string.
- To pass the address of a variable to a function. (In C++, you can also use a reference to do this.) By referencing a variable through its address, a function can change the contents of that variable.

The z/OS XL C compiler supports only the pointers that are obtained in one of the following ways:

- Directly from the return value of a library function which returns a pointer
- As an address of a variable
- From constants that refer to valid addresses or from the NULL constant
- Received as a parameter from another C function
- Directly from a call to a service in the z/OS IBM Language Environment® that allocates storage, such as CEEGTST

Any bitwise manipulation of a pointer can result in undefined behavior.

Note that the placement of the type qualifiers volatile and const affects the semantics of a pointer declaration. If either of the qualifiers appears before the *, the declarator describes a pointer to a type-qualified object. If either of the qualifiers appears between the * and the identifier, the declarator describes a type-qualified pointer.

The following table provides examples of pointer declarations.

<table>
<thead>
<tr>
<th>Declaration</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>long *pcoat;</td>
<td>pcoat is a pointer to an object having type long</td>
</tr>
<tr>
<td>extern short * const pvolt;</td>
<td>pvolt is a constant pointer to an object having type short</td>
</tr>
<tr>
<td>extern int volatile *pnut;</td>
<td>pnut is a pointer to an int object having the volatile qualifier</td>
</tr>
<tr>
<td>float * volatile psoup;</td>
<td>psoup is a volatile pointer to an object having type float</td>
</tr>
<tr>
<td>enum bird *pfowl;</td>
<td>pfowl is a pointer to an enumeration object of type bird</td>
</tr>
<tr>
<td>char (*)(pvish)(void);</td>
<td>pvish is a pointer to a function that takes no parameters and returns a char</td>
</tr>
</tbody>
</table>
Pointer arithmetic

You can perform a limited number of arithmetic operations on pointers. These operations are:

- Increment and decrement
- Addition and subtraction
- Comparison
- Assignment

The increment (++) operator increases the value of a pointer by the size of the data object the pointer refers to. For example, if the pointer refers to the second element in an array, the ++ makes the pointer refer to the third element in the array.

The decrement (--) operator decreases the value of a pointer by the size of the data object the pointer refers to. For example, if the pointer refers to the second element in an array, the -- makes the pointer refer to the first element in the array.

You can add an integer to a pointer but you cannot add a pointer to a pointer.

If the pointer p points to the first element in an array, the following expression causes the pointer to point to the third element in the same array:

\[ p = p + 2; \]

If you have two pointers that point to the same array, you can subtract one pointer from the other. This operation yields the number of elements in the array that separate the two addresses that the pointers refer to.

You can compare two pointers with the following operators: ==, !=, <, >, <=, and >=.

Pointer comparisons are defined only when the pointers point to elements of the same array. Pointer comparisons using the == and != operators can be performed even when the pointers point to elements of different arrays.

You can assign to a pointer the address of a data object, the value of another compatible pointer or the NULL pointer.
Type-based aliasing

The compiler follows the type-based aliasing rule in the C and C++ standards when the ANSIALIAS option is in effect (which it is by default). This rule, also known as the ANSI aliasing rule, states that a pointer can only be dereferenced to an object of the same type or a compatible type. The common coding practice of casting a pointer to an incompatible type and then dereferencing it violates this rule. (Note that char pointers are an exception to this rule.) Refer to the description of the ANSIALIAS option in the z/OS XL C/C++ User’s Guide for additional information.

The compiler uses the type-based aliasing information to perform optimizations to the generated code. Contravening the type-based aliasing rule can lead to unexpected behavior, as demonstrated in the following example:

```c
int *p;
double d = 0.0;

int *faa(double *g); /* cast operator inside the function */

void foo(double f) {
    p = faa(&f); /* turning &f into an int ptr */
    f += 1.0; /* compiler may discard this statement */
    printf("f=%x\n", *p);
}

int *faa(double *g) { return (int*) g; } /* questionable cast; */
/* the function can be in */
/* another translation unit */
```

1. The C Standard states that an object shall have its stored value accessed only by an lvalue that has one of the following types:
   • the declared type of the object,
   • a qualified version of the declared type of the object,
   • a type that is the signed or unsigned type corresponding to the declared type of the object,
   • a type that is the signed or unsigned type corresponding to a qualified version of the declared type of the object,
   • an aggregate or union type that includes one of the aforementioned types among its members (including, recursively, a member of a subaggregate or contained union), or
   • a character type

The C++ standard states that if a program attempts to access the stored value of an object through an lvalue of other than one of the following types, the behavior is undefined:
   • the dynamic type of the object,
   • a cv-qualified version of the dynamic type of the object,
   • a type that is the signed or unsigned type corresponding to the dynamic type of the object,
   • a type that is the signed or unsigned type corresponding to a cv-qualified version of the dynamic type of the object,
   • an aggregate or union type that includes one of the aforementioned types among its members (including, recursively, a member of a subaggregate or contained union), or
   • a type that is a (possible cv-qualified) base class type of the dynamic type of the object,
   • a char or unsigned char type.
In the above printf statement, *p cannot be dereferenced to a double under the ANSI aliasing rule. The compiler determines that the result of f += 1.0; is never used subsequently. Thus, the optimizer may discard the statement from the generated code. If you compile the above example with optimization enabled, the printf statement may output 0 (zero).

Compatibility of pointers (C only)

Two pointer types with the same type qualifiers are compatible if they point to objects of compatible types. The composite type for two compatible pointer types is the similarly qualified pointer to the composite type.

The following example shows compatible declarations for the assignment operation:

```c
float subtotal;
float * sub_ptr;
/* ... */
sub_ptr = &subtotal;
printf("The subtotal is \%f\n", *sub_ptr);
```

The next example shows incompatible declarations for the assignment operation:

```c
double league;
int * minor;
/* ... */
minor = &league; /* error */
```

Packed and nonpacked objects have different memory layouts. Consequently, a pointer to a packed structure or union is incompatible with a pointer to a corresponding nonpacked structure or union. As a result, comparisons and assignments between pointers to packed and nonpacked objects are not valid.

You can, however, perform these assignments and comparisons with type casts. In the following example, the cast operation lets you compare the two pointers, but you must be aware that ps1 still points to a nonpacked object:

```c
int main(void)
{
    _Packed struct ss *ps1;
    struct ss      *ps2;
    ...
    ps1 = (_Packed struct ss*) ps2;
    ...}
```
Arrays

An array is a collection of objects of the same data type, allocated contiguously in memory. Individual objects in an array, called elements, are accessed by their position in the array. The subscripting operator ([[]]) provides the mechanics for creating an index to array elements. This form of access is called indexing or subscripting. An array facilitates the coding of repetitive tasks by allowing the statements executed on each element to be put into a loop that iterates through each element in the array.

The C and C++ languages provide limited built-in support for an array type: reading and writing individual elements. Assignment of one array to another, the comparison of two arrays for equality, returning self-knowledge of size are not supported by either language.

The type of an array is derived from the type of its elements, in what is called array type derivation. If array objects are of incomplete type, the array type is also considered incomplete. Array elements may not be of type void or of function type. However, arrays of pointers to functions are allowed.

Array elements may not be of reference type or of an abstract class type.

The array declarator contains an identifier followed by an optional subscript declarator. An identifier preceded by an asterisk (*) is an array of pointers.

Array subscript declarator syntax

```markdown
constant_expression
```

The constant_expression is a constant integer expression, indicating the size of the array, which must be positive.

If the declaration appears in block or function scope, a nonconstant expression can be specified for the array subscript declarator, and the array is considered a variable-length array, as described in "Variable length arrays" on page 91.

The subscript declarator describes the number of dimensions in the array and the number of elements in each dimension. Each bracketed expression, or subscript, describes a different dimension and must be a constant expression.

The following example defines a one-dimensional array that contains four elements having type char:

```c
char
list[4];
```

The first subscript of each dimension is 0. The array list contains the elements:

```c
list[0]
list[1]
list[2]
list[3]
```

The following example defines a two-dimensional array that contains six elements of type int:

```c
int
roster[3][2];
```
Multidimensional arrays are stored in row-major order. When elements are referred to in order of increasing storage location, the last subscript varies the fastest. For example, the elements of array `roster` are stored in the order:

```
roster[0][0]
roster[0][1]
roster[1][0]
roster[1][1]
roster[2][0]
roster[2][1]
```

In storage, the elements of `roster` would be stored as:

```
| | |
|----------------|
|                |
|                |
roster[0][0]     roster[0][1]     roster[1][0]
```

You can leave the first (and only the first) set of subscript brackets empty in:

- Array definitions that contain initializations
- `extern` declarations
- Parameter declarations

In array definitions that leave the first set of subscript brackets empty, the initializer determines the number of elements in the first dimension. In a one-dimensional array, the number of initialized elements becomes the total number of elements. In a multidimensional array, the initializer is compared to the subscript declarator to determine the number of elements in the first dimension.

---

**Variable length arrays**

A variable length array, which is a C99 feature, is an array of automatic storage duration whose length is determined at run time.

**Variable length array declarator syntax**

```
array_identifier[ expression ]
type-qualifiers
```

If the size of the array is indicated by `*` instead of an expression, the variable length array is considered to be of unspecified size. Such arrays are considered complete types, but can only be used in declarations of function prototype scope.

A variable length array and a pointer to a variable length array are considered *variably modified types*. Declarations of variably modified types must be at either block scope or function prototype scope. Array objects declared with the `extern` storage class specifier cannot be of variable length array type. Array objects declared with the `static` storage class specifier can be a pointer to a variable length array, but not an actual variable length array. The identifiers declared with a variably modified type must be ordinary identifiers and therefore cannot be members of structures or unions. A variable length array cannot be initialized.
Note: In C++ applications, storage allocated for use by variable length arrays is not released until the function they reside in completes execution.

A variable length array can be the operand of a sizeof expression. In this case, the operand is evaluated at run time, and the size is neither an integer constant nor a constant expression, even though the size of each instance of a variable array does not change during its lifetime.

A variable length array can be used in a typedef statement. The typedef name will have only block scope. The length of the array is fixed when the typedef name is defined, not each time it is used.

A function parameter can be a variable length array. The necessary size expressions must be provided in the function definition. The compiler evaluates the size expression of a variably modified parameter on entry to the function. For a function declared with a variable length array as a parameter, as in the following,

```c
void f(int x, int a[][x]);
```

the size of the variable length array argument must match that of the function definition.

IBM The C++ extension does not include support for references to a variable length array type; neither may a function parameter be a reference to a variable length array type.

**Related reference**

Flexible array members (C only)

**Compatibility of arrays (C only)**

Two array types that are similarly qualified are compatible if the types of their elements are compatible. For example,

```c
char ex1[25];
const char ex2[25];
```

are not compatible.

The composite type of two compatible array types is an array with the composite element type. The sizes of both original types must be equivalent if they are known. If the size of only one of the original array types is known, then the composite type has that size. For example:

```c
char ex3[];
char ex4[42];
```

The composite type of ex3 and ex4 is char[42]. If one of the original types is a variable length array, the composite type is that type.

"External linkage" on page 7

**References (C++ only)**

A reference is an alias or an alternative name for an object. All operations applied to a reference act on the object to which the reference refers. The address of a reference is the address of the aliased object.

A reference type is defined by placing the reference modifier & after the type specifier. You must initialize all references except function parameters when they are defined. Once defined, a reference cannot be reassigned because it is an alias to its target. What happens when you try to reassign a reference turns out to be the assignment of a new value to the target.
Because arguments of a function are passed by value, a function call does not modify the actual values of the arguments. If a function needs to modify the actual value of an argument or needs to return more than one value, the argument must be **passed by reference** (as opposed to being **passed by value**). Passing arguments by reference can be done using either references or pointers. Unlike C, C++ does not force you to use pointers if you want to pass arguments by reference. The syntax of using a reference is somewhat simpler than that of using a pointer. Passing an object by reference enables the function to change the object being referred to without creating a copy of the object within the scope of the function. Only the address of the actual original object is put on the stack, not the entire object.

For example:

```c
int f(int&);
int main()
{
    extern int i;
    f(i);
}
```

You cannot tell from the function call `f(i)` that the argument is being passed by reference.

References to **NULL** are not allowed.

For information on references to functions, see "Pointers to functions" on page 218.

### Initializers

An **initializer** is an optional part of a data declaration that specifies an initial value of a data object. The initializers that are legal for a particular declaration depend on the type and storage class of the object to be initialized.

The initializer consists of the `=` symbol followed by an initial **expression** or a brace-enclosed list of initial expressions separated by commas. Individual expressions must be separated by commas, and groups of expressions can be enclosed in braces and separated by commas. Braces (`{ }`) are optional if the initializer for a character string is a string literal. The number of initializers must not be greater than the number of elements to be initialized. The initial expression evaluates to the first value of the data object.

To assign a value to an arithmetic or pointer type, use the simple initializer: `=` **expression**. For example, the following data definition uses the initializer `= 3` to set the initial value of `group` to 3:

```c
int group = 3;
```

You initialize a variable of character type with a character literal (consisting of one character) or with an expression that evaluates to an integer.

**C++** *(C++ only)* You can initialize variables at namespace scope with nonconstant expressions.

**C** You cannot initialize variables at global scope with nonconstant expressions.

"Initialization and storage classes" on page 94 discusses the rules for initialization according to the storage class of variables.
"Designated initializers for aggregate types (C only)" on page 95 describes designated initializers, which are a C99 feature that can be used to initialize arrays, structures, and unions.

The following sections discuss initialization for derived types:

- "Initialization of structures and unions" on page 97
- "Initialization of pointers" on page 100
- "Initialization of arrays" on page 100
- "Initialization of references (C++ only)" on page 103

### Initialization and storage classes

This topic includes descriptions of the following:

- Initialization of automatic variables
- Initialization of static variables
- Initialization of external variables
- Initialization of register variables

#### Initialization of automatic variables

You can initialize any `auto` variable except function parameters. If you do not explicitly initialize an automatic object, its value is indeterminate. If you provide an initial value, the expression representing the initial value can be any valid C or C++ expression. The object is then set to that initial value each time the program block that contains the object's definition is entered.

Note that if you use the `goto` statement to jump into the middle of a block, automatic variables within that block are not initialized.

**Note:** In C++0x, the keyword `auto` is no longer used as a storage class specifier. Instead, it is used as a type specifier. The compiler deduces the type of an `auto` variable from the type of its initializer expression. For more information, see "The auto type specifier (C++0x)" on page 67.

#### Initialization of static variables

You can initialize a `static` object with a constant expression, or an expression that reduces to the address of a previously declared `extern` or static object, possibly modified by a constant expression. If you do not explicitly initialize a `static` (or external) variable, it will have a value of zero of the appropriate type, unless it is a pointer, in which case it will be initialized to NULL.

C A static variable in a block is initialized only one time, prior to program execution, whereas an `auto` variable that has an initializer is initialized every time it comes into existence.

C++ A static variable in a block can be dynamically initialized when the flow of control passes through its definition in a block for the first time. Dynamic initialization of a static variable can occur with non-constant expressions. A static object of class type will use the default constructor if you do not initialize it.

#### Initialization of external variables

You can initialize any object with the `extern` storage class specifier at global scope in C or at namespace scope in C++. The initializer for an `extern` object must either:
• C++ Appear as part of the definition, and the initial value must be described by a constant expression;
• C++ Appear as part of the definition.
• Reduce to the address of a previously declared object with static storage duration. You may modify this object with pointer arithmetic. (In other words, you may modify the object by adding or subtracting an integral constant expression.)

If you do not explicitly initialize an extern variable, its initial value is zero of the appropriate type. Initialization of an extern object is completed by the time the program starts running.

Initialization of register variables

You can initialize any register object except function parameters. If you do not initialize an automatic object, its value is indeterminate. If you provide an initial value, the expression representing the initial value can be any valid C or C++ expression. The object is then set to that initial value each time the program block that contains the object's definition is entered.

Designated initializers for aggregate types (C only)

Designated initializers, a C99 feature, are supported for aggregate types, including arrays, structures, and unions. A designated initializer, or designator, points out a particular element to be initialized. A designator list is a comma-separated list of one or more designators. A designator list followed by an equal sign constitutes a designation.

Designated initializers allow for the following flexibility:
• Elements within an aggregate can be initialized in any order.
• The initializer list can omit elements that are declared anywhere in the aggregate, rather than only at the end. Elements that are omitted are initialized as if they are static objects: arithmetic types are initialized to 0; pointers are initialized to NULL.
• Where inconsistent or incomplete bracketing of initializers for multi-dimensional arrays or nested aggregates may be difficult to understand, designators can more clearly identify the element or member to be initialized.

Designator list syntax for structures and unions

```
-> ( .member = expression )
```

Designator list syntax for arrays

```
-> [ array subscript = expression ]
```

In the following example, the designator is .any_member and the designated initializer is .any_member = 13:

```c
union { /* ... */ } caw = { .any_member = 13 };
```
The following example shows how the second and third members b and c of structure variable klm are initialized with designated initializers:

```c
struct xyz {
    int a;
    int b;
    int c;
} klm = { .a = 99, .c = 100 };
```

In the following example, the third and second elements of the one-dimensional array aa are initialized to 3 and 6, respectively:

```c
```

The following example initializes the first four and last four elements, while omitting the middle four:

```c
```

The omitted four elements of grid are initialized to zero:

<table>
<thead>
<tr>
<th>Element</th>
<th>Value</th>
<th>Element</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>grid[0][0]</td>
<td>8</td>
<td>grid[1][2]</td>
<td>0</td>
</tr>
<tr>
<td>grid[0][1]</td>
<td>6</td>
<td>grid[1][3]</td>
<td>0</td>
</tr>
<tr>
<td>grid[0][2]</td>
<td>4</td>
<td>grid[2][0]</td>
<td>9</td>
</tr>
<tr>
<td>grid[0][3]</td>
<td>1</td>
<td>grid[2][1]</td>
<td>3</td>
</tr>
<tr>
<td>grid[1][0]</td>
<td>0</td>
<td>grid[2][2]</td>
<td>1</td>
</tr>
<tr>
<td>grid[1][1]</td>
<td>0</td>
<td>grid[2][3]</td>
<td>1</td>
</tr>
</tbody>
</table>

Designated initializers can be combined with regular initializers, as in the following example:

```c
int a[10] = {2, 4, [8]=9, 10}
```

In this example, a[0] is initialized to 2, a[1] is initialized to 4, a[2] to a[7] are initialized to 0, and a[9] is initialized to 10.

In the following example, a single designator is used to “allocate” space from both ends of an array:

```c
int a[MAX] = {
    1, 3, 5, 7, 9, [MAX-5] = 8, 6, 4, 2, 0
};
```

The designated initializer, [MAX-5] = 8, means that the array element at subscript MAX-5 should be initialized to the value 8. If MAX is 15, a[5] through a[9] will be initialized to zero. If MAX is 7, a[2] through a[4] will first have the values 5, 7, and 9, respectively, which are overridden by the values 8, 6, and 4. In other words, if MAX is 7, the initialization would be the same as if the declaration had been written:

```c
int a[MAX] = {
    1, 3, 8, 6, 4, 2, 0
};
```

You can also use designators to represent members of nested structures. For example:

```c
struct a {
    struct b {
        int c;
        int d;
    } e;
    float f;
} g = { .e.c = 3 };
```
initializes member c of structure variable e, which is a member of structure variable g, to the value of 3.

Related reference

"Initialization of structures and unions" on page 100

"Initialization of arrays" on page 100

Initialization of structures and unions

An initializer for a structure is a brace-enclosed comma-separated list of values, and for a union, a brace-enclosed single value. The initializer is preceded by an equal sign (=).

C99 and C++ allow the initializer for an automatic member variable of a union or structure type to be a constant or non-constant expression.

C++ The initializer for a static member variable of a union or structure type must be a constant expression or string literal. See "Static data members" on page 265 for more information.

There are two ways to specify initializers for structures and unions:

- With C89-style initializers, structure members must be initialized in the order declared, and only the first member of a union can be initialized.

- Using designated initializers, a C99 feature which allows you to name members to be initialized, structure members can be initialized in any order, and any (single) member of a union can be initialized. Designated initializers are described in detail in "Designated initializers for aggregate types (C only)" on page 95.

Using C89-style initialization, the following example shows how you would initialize the first union member birthday of the union variable people:

```c
union {
    char birthday[9];
    int age;
    float weight;
} people = {"23/07/57"};
```

Using a designated initializer in the same example, the following initializes the second union member age:

```c
union {
    char birthday[9];
    int age;
    float weight;
} people = {.age = 14};
```

The following definition shows a completely initialized structure:

```c
struct address {
    int street_no;
    char *street_name;
    char *city;
    char *prov;
    char *postal_code;
};
static struct address perm_address = {
    3, "Savona Dr.", "Dundas", "Ontario", "L4B 2A1"};
```

The values of perm_address are:

<table>
<thead>
<tr>
<th>Member</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>perm_address.street_no</td>
<td>3</td>
</tr>
</tbody>
</table>
Unnamed structure or union members do not participate in initialization and have indeterminate value after initialization. Therefore, in the following example, the bit field is not initialized, and the initializer 3 is applied to member b:

```c
struct {
    int a;
    int :10;
    int b;
} w = { 2, 3 };
```

You do not have to initialize all members of a structure or union; the initial value of uninitialized structure members depends on the storage class associated with the structure or union variable. In a structure declared as static, any members that are not initialized are implicitly initialized to zero of the appropriate type; the members of a structure with automatic storage have no default initialization. The default initializer for a union with static storage is the default for the first component; a union with automatic storage has no default initialization.

The following definition shows a partially initialized structure:

```c
struct address {
    int street_no;
    char *street_name;
    char *city;
    char *prov;
    char *postal_code;
};
```

```c
struct address temp_address =
    { 44, "Knyvet Ave.", "Hamilton", "Ontario" };
```

The values of `temp_address` are:

<table>
<thead>
<tr>
<th>Member</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>temp_address.street_no</td>
<td>44</td>
</tr>
<tr>
<td>temp_address.street_name</td>
<td>address of string &quot;Knyvet Ave.&quot;</td>
</tr>
<tr>
<td>temp_address.city</td>
<td>address of string &quot;Hamilton&quot;</td>
</tr>
<tr>
<td>temp_address.prov</td>
<td>address of string &quot;Ontario&quot;</td>
</tr>
<tr>
<td>temp_address.postal_code</td>
<td>Depends on the storage class of the temp_address variable; if it is static, the value would be NULL.</td>
</tr>
</tbody>
</table>

To initialize only the third and fourth members of the `temp_address` variable, you could use a designated initializer list, as follows:

```c
struct address {
    int street_no;
    char *street_name;
    char *city;
    char *prov;
    char *postal_code;
};
```

```c
struct address temp_address =
    { .city = "Hamilton", .prov = "Ontario" };
```
Initialization of enumerations

The initializer for an enumeration variable contains the = symbol followed by an expression enumeration_constant.

In C++, the initializer must have the same type as the associated enumeration type.

Example

The following example shows the initialization of enumerations.

// Declares an unscoped enumeration "grain".
enum grain { oats, wheat, barley, corn, rice };

// Defines the variable "g_food" and gives "g_food" the initial value of "barley" (the integer value associated with barley is 2).
enum grain g_food = barley;

Example

// Declares an unscoped enumeration "color".
enum color { white, yellow, green, red, brown };

// Declares a scoped enumeration "light".
enum class light { A, B, C, D };

// Valid, defines the variable "light1", and gives "light1" the initial value of "A" (the integer value associated with "A" is 0)
light light1 = light :: A;

// Valid, the keyword "enum" is optional and can be omitted.
enum light light2 = light :: B;

// Invalid, the scoped enumerator "A" must be qualified with its enumeration's name, because it belongs to the enumeration's scope and cannot be referenced directly outside of the enumeration's scope.
light light3 = A;

// Valid, the "white" enumerator is visible here, because "color" is an unscoped enumeration.
color color1 = white;

color color2 = color :: yellow; // valid

// Invalid, you cannot initialize an enumeration with an integer or enumeration constant from a different enumeration, without an explicit cast.
light light4 = color :: white;

light light5 = (light) color :: red; // valid, explicit cast is allowed.
Initialization of pointers

The initializer is an = (equal sign) followed by the expression that represents the address that the pointer is to contain. The following example defines the variables time and speed as having type double and amount as having type pointer to a double. The pointer amount is initialized to point to total:

```c
double time, speed, *amount = &total;
```

The compiler converts an unsubscripted array name to a pointer to the first element in the array. You can assign the address of the first element of an array to a pointer by specifying the name of the array. The following two sets of definitions are equivalent. Both define the pointer student and initialize student to the address of the first element in section:

```c
int section[80];
int *student = section;
```

is equivalent to:

```c
int section[80];
int *student = &section[0];
```

You can assign the address of the first character in a string constant to a pointer by specifying the string constant in the initializer. The following example defines the pointer variable string and the string constant "abcd". The pointer string is initialized to point to the character a in the string "abcd".

```c
char *string = "abcd";
```

The following example defines weekdays as an array of pointers to string constants. Each element points to a different string. The pointer weekdays[2], for example, points to the string "Tuesday".

```c
static char *weekdays[] =
{    
    "Sunday", "Monday", "Tuesday", "Wednesday",    
    "Thursday", "Friday", "Saturday"    
};
```

A pointer can also be initialized to null using any integer constant expression that evaluates to 0, for example `char * a=0;`. Such a pointer is a null pointer. It does not point to any object.

"Pointers" on page 86

Initialization of arrays

The initializer for an array is a comma-separated list of constant expressions enclosed in braces ({ }). The initializer is preceded by an equal sign (=). You do not need to initialize all elements in an array. If an array is partially initialized, elements that are not initialized receive the value 0 of the appropriate type. The same applies to elements of arrays with static storage duration. (All file-scope variables and function-scope variables declared with the static keyword have static storage duration.)

There are two ways to specify initializers for arrays:

- With C89-style initializers, array elements must be initialized in subscript order.
- Using designated initializers, which allow you to specify the values of the subscript elements to be initialized, array elements can be initialized in any order. Designated initializers are described in detail in "Designated initializers for aggregate types (C only)" on page 95.

Using C89-style initializers, the following definition shows a completely initialized one-dimensional array:
static int number[3] = { 5, 7, 2 };

The array number contains the following values: number[0] is 5, number[1] is 7; number[2] is 2. When you have an expression in the subscript declarator defining the number of elements (in this case 3), you cannot have more initializers than the number of elements in the array.

The following definition shows a partially initialized one-dimensional array:
static int number1[3] = { 5, 7 };

The values of number1[0] and number1[1] are the same as in the previous definition, but number1[2] is 0.

The following definition shows how you can use designated initializers to skip over elements of the array that you don't want to initialize explicitly:

The array number contains the following values: number[0] is 5; number[1] is implicitly initialized to 0; number[2] is 7.

Instead of an expression in the subscript declarator defining the number of elements, the following one-dimensional array definition defines one element for each initializer specified:
static int item[] = { 1, 2, 3, 4, 5 };

The compiler gives item the five initialized elements, because no size was specified and there are five initializers.

**Initialization of character arrays**

You can initialize a one-dimensional character array by specifying:

- A brace-enclosed comma-separated list of constants, each of which can be contained in a character
- A string constant (braces surrounding the constant are optional)

Initializing a string constant places the null character (\0) at the end of the string if there is room or if the array dimensions are not specified.

The following definitions show character array initializations:

```
static char name1[] = { 'J', 'a', 'n' };
static char name2[] = { "Jan" };
static char name3[4] = "Jan";
```

These definitions create the following elements:

<table>
<thead>
<tr>
<th>Element</th>
<th>Value</th>
<th>Element</th>
<th>Value</th>
<th>Element</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>name1[0]</td>
<td>J</td>
<td>name2[0]</td>
<td>J</td>
<td>name3[0]</td>
<td>J</td>
</tr>
<tr>
<td></td>
<td></td>
<td>name2[3]</td>
<td>\0</td>
<td>name3[3]</td>
<td>\0</td>
</tr>
</tbody>
</table>

Note that the following definition would result in the null character being lost:

```
static char name3[3]="Jan";
```
When you initialize an array of characters with a string, the number of characters in the string — including the terminating '\0' — must not exceed the number of elements in the array.

Initialization of multidimensional arrays

You can initialize a multidimensional array using any of the following techniques:

- Listing the values of all elements you want to initialize, in the order that the compiler assigns the values. The compiler assigns values by increasing the subscript of the last dimension fastest. This form of a multidimensional array initialization looks like a one-dimensional array initialization. The following definition completely initializes the array `month_days`:

  ```
  static month_days[2][12] =
  {
    31, 28, 31, 30, 31, 30, 31, 30, 31, 30, 31,
    31, 29, 31, 30, 31, 30, 31, 31, 30, 31, 30, 31
  };
  ```

- Using braces to group the values of the elements you want initialized. You can put braces around each element, or around any nesting level of elements. The following definition contains two elements in the first dimension (you can consider these elements as rows). The initialization contains braces around each of these two elements:

  ```
  static int month_days[2][12] =
  {
    { 31, 28, 31, 30, 31, 30, 31, 31, 30, 31, 30, 31 },
    { 31, 29, 31, 30, 31, 30, 31, 31, 30, 31, 30, 31 }
  };
  ```

- Using nested braces to initialize dimensions and elements in a dimension selectively. In the following example, only the first eight elements of the array `grid` are explicitly initialized. The remaining four elements that are not explicitly initialized are automatically initialized to zero.

  ```
  static short grid[3] [4] = {8, 6, 4, 1, 9, 3, 1, 1};
  ```

  The initial values of `grid` are:

<table>
<thead>
<tr>
<th>Element</th>
<th>Value</th>
<th>Element</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>grid[0] [0]</td>
<td>8</td>
<td>grid[1] [2]</td>
<td>1</td>
</tr>
<tr>
<td>grid[0] [1]</td>
<td>6</td>
<td>grid[1] [3]</td>
<td>1</td>
</tr>
<tr>
<td>grid[0] [2]</td>
<td>4</td>
<td>grid[2] [0]</td>
<td>0</td>
</tr>
<tr>
<td>grid[0] [3]</td>
<td>1</td>
<td>grid[2] [1]</td>
<td>0</td>
</tr>
<tr>
<td>grid[1] [0]</td>
<td>9</td>
<td>grid[2] [2]</td>
<td>0</td>
</tr>
</tbody>
</table>

  - Using designated initializers. The following example uses designated initializers to explicitly initialize only the last four elements of the array. The first eight elements that are not explicitly initialized are automatically initialized to zero.

    ```
    ```

    The initial values of `grid` are:

    | Element   | Value | Element   | Value |
    |-----------|-------|-----------|-------|
    | grid[0] [0] | 0     | grid[1] [2] | 0     |
    | grid[0] [1] | 0     | grid[1] [3] | 0     |
    | grid[0] [2] | 0     | grid[2] [0] | 8     |
    | grid[0] [3] | 0     | grid[2] [1] | 6     |

**Initialization of references (C++ only)**

The object that you use to initialize a reference must be of the same type as the reference, or it must be of a type that is convertible to the reference type. If you initialize a reference to a constant using an object that requires conversion, a temporary object is created. In the following example, a temporary object of type float is created:

```cpp
int i;
const float& f = i; // reference to a constant float
```

When you initialize a reference with an object, you bind that reference to that object.

Attempting to initialize a nonconstant reference with an object that requires a conversion is an error.

Once a reference has been initialized, it cannot be modified to refer to another object. For example:

```cpp
int num1 = 10;
int num2 = 20;

int &RefOne = num1; // valid
int &RefOne = num2; // error, two definitions of RefOne
RefOne = num2; // assign num2 to num1
int &RefTwo; // error, uninitialized reference
int &RefTwo = num2; // valid
```

Note that the initialization of a reference is not the same as an assignment to a reference. Initialization operates on the actual reference by initializing the reference with the object it is an alias for. Assignment operates through the reference on the object referred to.

A reference can be declared without an initializer:

- When it is used in a parameter declaration
- In the declaration of a return type for a function call
- In the declaration of class member within its class declaration
- When the extern specifier is explicitly used

You cannot have references to any of the following:

- Other references
- Bit fields
- Arrays of references
- Pointers to references

**Direct binding**

Suppose a reference r of type T is initialized by an expression e of type U.

The reference r is bound directly to e if the following statements are true:

- Expression e is an lvalue
• T is the same type as U, or T is a base class of U
• T has the same, or more, const or volatile qualifiers than U

The reference r is also bound directly to e if e can be implicitly converted to a type such that the previous list of statements is true.

Declarator qualifiers

z/OS XL C/C++ includes two additional qualifiers that are given in declarator specifications:

- C _Packed.
- C++ _Export

The _Packed qualifier (C only)

The z/OS XL C compiler aligns structure and union members according to their natural byte boundaries and ends the structure or union on its natural boundary. However, since the alignment of a structure or union is that of the member with the largest alignment requirement, the compiler may add padding to elements whose byte boundaries are smaller than this requirement. You can use the _Packed qualifier to remove padding between members of structures or unions. Packed and nonpacked structures and unions have different storage layouts.

Consider the following example:

```c
union uu{
    short   a;
    struct {
        char x;
        char y;
        char z;
    } b;
};
union uu    nonpacked[2];
_Packed union uu    packed[2];
```

In the array of unions nonpacked, since the largest alignment requirement among the union members is that of short a, namely, 2 bytes, one byte of padding is added at the end of each union in the array to enforce this requirement:

```
0 1 2 3 4 5 6 7 8
x y z x y z
```

In the array of unions packed, each union has a length of only 3 bytes, as opposed to the 4 bytes of the previous case:

```
0 1 2 3 4 5 6
x y z x y z
```
Note: When the _Packed qualifier is used, the compiler removes padding between members of structures or unions, regardless of the member type.

If you specify the _Packed qualifier on a structure or union that contains a structure or union as a member, the qualifier is not passed on to the nested structure or union.

Related reference
“Compatibility of structures, unions, and enumerations (C only)” on page 65
“#pragma pack” on page 459

The _Export qualifier (C++ only)

You can use the _Export keyword with a function name or external variable to declare that it is to be exported (made available to other modules). The _Export keyword must immediately precede the object name. For more information, see “The _Export function specifier (C++ only)” on page 197.

“External linkage” on page 7
“#pragma export” on page 431

Variable attributes (IBM extension)

A variable attribute is a language extension that allows you to use a named attribute to specify special properties of variables. Currently, only the variable attribute aligned is supported on the z/OS platform.

A variable attribute is specified with the keyword __attribute__ followed by the attribute name and any additional arguments the attribute name requires. A variable __attribute__ specification is included in the declaration of a variable, and can be placed before or after the declarator. Although there are variations, the syntax generally takes either of the following forms:

Variable attribute syntax: post-declarator

| declarator | __attribute__ | ( | _attribute name_ | ) |

Variable attribute syntax: pre-declarator

| type specifier | __attribute__ | ( | _attribute name_ | ) | declarator | initializer |

The _attribute name can be specified with or without leading and trailing double underscore characters; however, using the double underscore reduces the likelihood of a name conflict with a macro of the same name. For unsupported attribute names, the z/OS XL C/C++ compiler issues diagnostics and ignores the attribute specification. Multiple attribute names can be specified in the same attribute specification.

In a comma-separated list of declarators on a single declaration line, if a variable attribute appears before all the declarators, it applies to all declarators in the declaration. If the attribute appears after a declarator, it only applies to the immediately preceding declarator. For example:

```c
struct A {
    int b __attribute__((aligned)); /* typical placement of variable */
    /* attribute */
```
int __attribute__((aligned)) c = 10; /* variable attribute can also be */ /* placed here */

int d, e, f __attribute__((aligned)); /* attribute applies to f only */

int g __attribute__((aligned)), h, i; /* attribute applies to g only */

int __attribute__((aligned)) j, k, l; /* attribute applies to j, k, and l */

};

The aligned variable attribute

With the aligned variable attribute, you can override the default memory alignment mode to specify a minimum memory alignment value, expressed as a number of bytes, for any of the following types of variables:

- Non-aggregate variables
- Aggregate variables (such as a structures, classes, or unions)
- Selected member variables

The attribute is typically used to increase the alignment of the given variable.

aligned variable attribute syntax

```
__attribute__((aligned(alignment_factor)))
```

The alignment_factor is the number of bytes, specified as a constant expression that evaluates to a positive power of 2. On the z/OS platform, the maximum supported value is 8 bytes in 32-bit mode, and 16 bytes in 64-bit mode. If you omit the alignment factor (and its enclosing parentheses), the compiler automatically uses the platform maximum. If you specify an alignment factor greater than the maximum, the compiler uses the default alignment in effect and ignores your specification.

When you apply the aligned attribute to a member variable in a bit field structure, the attribute specification is applied to the bit field container. If the default alignment of the container is greater than the alignment factor, the default alignment is used.

Example

In the following example, the structures first_address and second_address are set to an alignment of 16 bytes:

```
struct address {
    int street_no;
    char *street_name;
    char *city;
    char *prov;
    char *postal_code;
} first_address __attribute__((__aligned__(16))) ;

struct address second_address __attribute__((__aligned__(16))) ;
```

In the following example, only the members first_address.prov and first_address.postal_code are set to an alignment of 16 bytes:

```
struct address {
    int street_no;
    char *street_name;
    char *city;
    char *prov __attribute__((__aligned__(16))) ;
    char *postal_code __attribute__((__aligned__(16))) ;
} first_address ;
```
Chapter 5. Type conversions

An expression of a given type is *implicitly converted* in the following situations:

- The expression is used as an operand of an arithmetic or logical operation.
- The expression is used as a condition in an *if* statement or an iteration statement (such as a *for* loop). The expression will be converted to a Boolean (or an integer in C89).
- The expression is used in a *switch* statement. The expression will be converted to an integral type.
- The expression is used as an initialization. This includes the following:
  - An assignment is made to an lvalue that has a different type than the assigned value.
  - A function is provided an argument value that has a different type than the parameter.
  - The value specified in the *return* statement of a function has a different type from the defined return type for the function.

You can perform *explicit* type conversions using a *cast* expression, as described in “Cast expressions” on page 146.

**Vector type casts (IBM extension)**

Vector types can be cast to other vector types. The cast does not perform a conversion: it preserves the 128-bit pattern, but not necessarily the value. A cast between a vector type and a scalar type is not allowed.

Vector pointers and pointers to non-vector types can be cast back and forth to each other. When a pointer to a non-vector type is cast to a vector pointer, the address should be 16-byte aligned. The referenced object of the pointer to a non-vector type can be aligned on a sixteen-byte boundary by using either the `_align` specifier or `_attribute__((aligned(16)))`.

**Arithmetic conversions and promotions**

The following sections discuss the rules for the standard conversions for arithmetic types:

- “Integral conversions”
- “Floating-point conversions” on page 108
- “Boolean conversions” on page 108
- “z/OS Packed decimal conversions (C only)” on page 109

If two operands in an expression have different types, they are subject to the rules of the *usual arithmetic conversions*, as described in “Usual arithmetic conversions” on page 109.

**Integral conversions**

**Unsigned integer to unsigned integer or signed integer to signed integer**

If the types are identical, there is no change. If the types are of a different size, and the value can be represented by the new type, the value is not changed; if the value cannot be represented by the new type, truncation or sign shifting will occur.
Signed integer to unsigned integer
The resulting value is the smallest unsigned integer type congruent to the source integer. If the value cannot be represented by the new type, truncation or sign shifting will occur.

Unsigned integer to signed integer
If the signed type is large enough to hold the original value, there is no change. If the value can be represented by the new type, the value is not changed; if the value cannot be represented by the new type, truncation or sign shifting will occur.

Signed and unsigned character types to integer
If the original value can be represented by int, it is represented as int. If the value cannot be represented by int, it is promoted to unsigned int.

Wide character type wchar_t to integer
If the original value can be represented by int, it is represented as int. If the value cannot be represented by int, it is promoted to the smallest type that can hold it: unsigned int, long, or unsigned long.

Signed and unsigned integer bit field to integer
If the original value can be represented by int, it is represented as int. If the value cannot be represented by int, it is promoted to unsigned int.

Enumeration type to integer
If the original value can be represented by int, it is represented as int. If the value cannot be represented by int, it is promoted to the smallest type that can hold it: unsigned int, long, or unsigned long. Note that an enumerated type can be converted to an integral type, but an integral type cannot be converted to an enumeration.

Boolean conversions
An unscoped enumeration, pointer, or pointer to member type can be converted to a Boolean type.

C
If the scalar value is equal to 0, the Boolean value is 0; otherwise, the Boolean value is 1.

C++
A zero, null pointer, or null member pointer value is converted to false. All other values are converted to true.

Floating-point conversions
The standard rule for converting between real floating-point types is as follows:

If the value being converted can be represented exactly in the new type, it is unchanged. If the value being converted is in the range of values that can be represented but cannot be represented exactly, the result is rounded, according to the current compile-time or runtime rounding mode in effect. If the value being converted is outside the range of values that can be represented, the result is dependent on the rounding mode.

Integer to floating point
If the value being converted can be represented exactly in the new type, it is unchanged. If the value being converted is in the range of values that can be represented but cannot be represented exactly, the result is correctly rounded. If the value being converted is outside the range of values that can be represented, the result is quiet NaN.

Floating point to integer
The fractional part is discarded (i.e., the value is truncated toward zero). If the value of the integral part cannot be represented by the integer type, the result is one of the following:

• If the integer type is unsigned, the result is the largest representable number if the floating-point number is positive, or 0 otherwise.
• If the integer type is signed, the result is the most negative or positive representable number according to the sign of the floating-point number.

Complex conversions

Complex to complex
If the types are identical, there is no change. If the types are of a different size, and the value can be represented by the new type, the value is not changed; if the value cannot be represented by the new type, both real and imaginary parts are converted according to the standard conversion rule given above.

Complex to real (binary)
The imaginary part of the complex value is discarded. If necessary, the value of the real part is converted according to the standard conversion rule given above.

Real (binary) to complex
The source value is used as the real part of the complex value, and converted, if necessary, according to the standard conversion rule given above. The value of the imaginary part is zero.

Packed decimal conversions (C only)

Packed decimal to long long integer
The fractional part is discarded.

Long long integer to packed decimal
The resulting size is decimal(20,0).

Complex to packed decimal
Only the floating value of the real part is used.

Packed decimal to complex
The real part of the complex type is converted, and the imaginary part is 0.

Packed decimal to decimal floating-point
If the number of significant digits in the packed decimal value exceeds the precision of the target, the result is rounded to the target precision using the current decimal floating-point rounding mode.

Decimal floating-point to packed decimal
Before conversion, the decimal floating-point value is rounded or truncated to match the fractional precision of the resulting type, if necessary. If the value being converted represents infinity or NaN, or if non-zero digits are truncated from the left end of the result, the result is undefined.

Usual arithmetic conversions

When different arithmetic types are used as operands in certain types of expressions, standard conversions known as usual arithmetic conversions are applied.

For example, when the values of two different integral types are added together, both values are first converted to the same type: when a short int value and an int value are added together, the short int value is converted to the int type. Chapter 6, “Expressions and operators,” on page 117 provides a list of the operators and expressions that participate in the usual arithmetic conversions.

Conversion ranks for arithmetic types

The ranks in the tables are listed from highest to lowest:

Table 20. Conversion ranks for floating-point types

<table>
<thead>
<tr>
<th>Operand type</th>
</tr>
</thead>
<tbody>
<tr>
<td>long double or long double _Complex</td>
</tr>
</tbody>
</table>
Table 20. Conversion ranks for floating-point types (continued)

<table>
<thead>
<tr>
<th>Operand type</th>

</table>

Table 22. Conversion ranks for integer types

<table>
<thead>
<tr>
<th>Operand type</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>long long int</code>, <code>unsigned long long int</code></td>
</tr>
<tr>
<td><code>long int</code>, <code>unsigned long int</code></td>
</tr>
<tr>
<td><code>int</code>, <code>unsigned int</code></td>
</tr>
<tr>
<td><code>short int</code>, <code>unsigned short int</code></td>
</tr>
<tr>
<td><code>char</code>, <code>signed char</code>, <code>unsigned char</code></td>
</tr>
<tr>
<td>Boolean</td>
</tr>
</tbody>
</table>

Notes:
- The `long long int` and `unsigned long long int` types are not included in the C89, C++98 and C++03 standards.
- The `wchar_t` type is not a distinct type, but rather a typedef for an integer type. The rank of the `wchar_t` type is equal to the rank of its underlying type.
- The rank of enumerated type is equal to the rank of its underlying type.

Rules for decimal floating-point operands

In a context where an operation involves two operands, if one of the operands is of decimal floating type, the other operand cannot be a generic floating type, imaginary type, or complex type. The compiler performs the usual arithmetic conversions to bring these two operands to a common type. The floating-point promotions are applied to both operands and the following rules apply to the promoted operands:

1. If both operands have the same type, no conversion is needed.
2. If one operand has the `_Decimal128` type, the other operand is converted to `_Decimal128`.
3. Otherwise, if one operand has the `_Decimal64` type, the other operand is converted to `_Decimal64`.
4. Otherwise, if one operand has the `_Decimal32` type, the other operand is converted to `_Decimal32`.

Rules for other floating-point operands

In a context where an operation involves two operands, if either of the operands is of floating-point type, the compiler performs the usual arithmetic conversions to bring these two operands to a common type. The floating-point promotions are applied to both operands. If the rules for decimal floating-point operands do not apply, the following rules apply to the promoted operands:

1. If both operands have the same type, no conversion is needed.
2. Otherwise, if both operands have complex types, the type at a lower integer conversion rank is converted to the type at a higher rank. For more information, see “floating-point conversions” on page 108.
3. Otherwise, if one operand has a complex type, the type of both operands after conversion is the higher rank of the following types:
   - The complex type corresponding to the type of the generic floating-point operand
   - The type of the complex operand

   For more information, see “floating-point conversions” on page 108.
4. Otherwise, both operands have generic floating types. The following rules apply:
   a. If one operand has the long double type, the other operand is converted to long double.
   b. Otherwise, if one operand has the double type, the other operand is converted to double.
   c. Otherwise, if one operand has the float type, the other operand is converted to float.

Rules for integral operands

In a context where an operation involves two operands, if both of the operands are of integral types, the compiler performs the usual arithmetic conversions to bring these two operands to a common type. The integral promotions are applied to both operands and the following rules apply to the promoted operands:

1. If both operands have the same type, no conversion is needed.
2. Otherwise, if both operands have signed integer types or both have unsigned integer types, the type at a lower integer conversion rank is converted to the type at a higher rank.
3. Otherwise, if one operand has an unsigned integer type and the other operand has a signed integer type, the following rules apply:
   a. If the rank for the unsigned integer type is higher than or equal to the rank for the signed integer type, the signed integer type is converted to the unsigned integer type.
   b. Otherwise, if the signed integer type can represent all of the values of the unsigned integer type, the unsigned integer type is converted to the signed integer type.
   c. Otherwise, both types are converted to the unsigned integer type that corresponds to the signed integer type.

Integral and floating-point promotions

The integral and floating-point promotions are used automatically as part of the usual arithmetic conversions and default argument promotions. The integral and floating-point promotions do not change either the sign or the magnitude of the value. For more information about the usual arithmetic conversions, see “Usual arithmetic conversions” on page 109.
Integral promotion rules for wchar_t

If a value is of the wchar_t type, the type of the value can be converted to the first of the following types that can represent all the values of the underlying type of wchar_t:

- int
- unsigned int
- long int
- unsigned long int
- long long int
- unsigned long long int

If none of the types in the list can represent all the values of the underlying type of wchar_t, the wchar_t type is converted to the underlying type of wchar_t.

Integral promotion rules for bit field

The rules apply to the following conditions:

- The -qupconv option is in effect.
- The type of an integral bit field is unsigned.
- The type of the integral bit field is smaller than the int type.

If all these conditions are satisfied, one of the following rules applies to the promotion of the integral bit field:

- If the unsigned int type can represent all the values of the integral bit field, the bit field is converted to unsigned int.
- Otherwise, no integral promotion applies to the bit field.

If any of these conditions is not satisfied, one of the following rules applies to the promotion of the integral bit field:

- If the int type can represent all the values of the integral bit field, the bit field is converted to int.
- Otherwise, if the unsigned int type can represent all the values, the bit field is converted to unsigned int.
- Otherwise, no integral promotion applies to the bit field.
Integral promotion rules for Boolean

If the -qupconv option is in effect, a Boolean value is converted to the unsigned int type with its value unchanged. Otherwise, if the -qnoupconv option is in effect, a Boolean value is converted to the int type with its value unchanged.

If a Boolean value is false, it is converted to an int with a value of 0. If a Boolean value is true, it is converted to an int with a value of 1.

Integral promotion rules for other types

The rules apply to the following conditions:
- The -qupconv option is in effect.
- The type of an integer type other than bit field and Boolean is unsigned.
- The type of the integer type is smaller than the int type.

If all these conditions are satisfied, the integer type is converted to the unsigned int type.

If any of these conditions is not satisfied, one of the following rules applies to the promotion of the integer type:
- If the integer type can be represented by the int type and its rank is lower than the rank of int, the integer type is converted to the int type.
- Otherwise, the integer type is converted to the unsigned int type.

floating-point promotion rules

The float type can be converted to the double type. The float value is not changed after the promotion.

Lvalue-to-rvalue conversions

If an lvalue appears in a situation in which the compiler expects an rvalue, the compiler converts the lvalue to an rvalue. The following table lists exceptions to this:

<table>
<thead>
<tr>
<th>Situation before conversion</th>
<th>Resulting behavior</th>
</tr>
</thead>
<tbody>
<tr>
<td>The lvalue is a function type.</td>
<td></td>
</tr>
<tr>
<td>The lvalue is an array.</td>
<td></td>
</tr>
<tr>
<td>The type of the lvalue is an incomplete type.</td>
<td>compile-time error</td>
</tr>
<tr>
<td>The lvalue refers to an uninitialized object.</td>
<td>undefined behavior</td>
</tr>
<tr>
<td>The lvalue refers to an object not of the type of the rvalue, nor of a type derived from the type of the rvalue.</td>
<td>undefined behavior</td>
</tr>
</tbody>
</table>

- C++ The lvalue is a nonclass type, qualified by either const or volatile. The type after conversion is not qualified by either const or volatile.
Pointer conversions

Pointer conversions are performed when pointers are used, including pointer assignment, initialization, and comparison.

Converts that involve pointers must use an explicit type cast. The exceptions to this rule are the allowable assignment conversions for C pointers. In the following table, a const-qualified lvalue cannot be used as a left operand of the assignment.

### Table 23. Legal assignment conversions for C pointers

<table>
<thead>
<tr>
<th>Left operand type</th>
<th>Permitted right operand types</th>
</tr>
</thead>
<tbody>
<tr>
<td>pointer to (object) T</td>
<td>• the constant 0</td>
</tr>
<tr>
<td></td>
<td>• a pointer to a type compatible with T</td>
</tr>
<tr>
<td></td>
<td>• a pointer to void (void*)</td>
</tr>
<tr>
<td>pointer to (function) F</td>
<td>• the constant 0</td>
</tr>
<tr>
<td></td>
<td>• a pointer to a function compatible with F</td>
</tr>
</tbody>
</table>

The referenced type of the left operand must have the same qualifiers as the right operand. An object pointer may be an incomplete type if the other pointer has type `void*`.

### Zero constant to null pointer

A constant expression that evaluates to zero is a null pointer constant. This expression can be converted to a pointer. This pointer will be a null pointer (pointer with a zero value), and is guaranteed not to point to any object.

### Array to pointer

An lvalue or rvalue with type "array of \( N \)," where \( N \) is the type of a single element of the array, to \( N* \). The result is a pointer to the initial element of the array. A conversion cannot be performed if the expression is used as the operand of the & (address) operator or the sizeof operator.

### Function to pointer

An lvalue that is a function can be converted to an rvalue that is a pointer to a function of the same type, except when the expression is used as the operand of the & (address) operator, the () (function call) operator, or the sizeof operator.
Conversion to void*

C pointers are not necessarily the same size as type int. Pointer arguments given to functions should be explicitly cast to ensure that the correct type expected by the function is being passed. The generic object pointer in C is void*, but there is no generic function pointer.

Any pointer to an object, optionally type-qualified, can be converted to void*, keeping the same const or volatile qualifications.

```
\begin{itemize}
  \item C The allowable assignment conversions involving void* as the left operand are shown in the following table.
  \end{itemize}

\begin{table}[h]
\centering
\caption{Legal assignment conversions in C for void*}
\begin{tabular}{|l|l|}
\hline
Left operand type & Permitted right operand types \\
\hline
(void*) & • The constant 0. \\
 & • A pointer to an object. The object may be of incomplete type. \\
 & • (void*) \\
\hline
\end{tabular}
\end{table}
```

```
\begin{itemize}
  \item C++ Pointers to functions cannot be converted to the type void* with a standard conversion: this can be accomplished explicitly, provided that a void* has sufficient bits to hold it.
  \end{itemize}

"The void type" on page 54
```

Reference conversions (C++ only)

A reference conversion can be performed wherever a reference initialization occurs, including reference initialization done in argument passing and function return values. A reference to a class can be converted to a reference to an accessible base class of that class as long as the conversion is not ambiguous. The result of the conversion is a reference to the base class subobject of the derived class object.

Reference conversion is allowed if the corresponding pointer conversion is allowed.
Qualification conversions (C++ only)

An type-qualified rvalue of any type, containing zero or more const or volatile qualifications, can be converted to an rvalue of type-qualified type where the second rvalue contains more const or volatile qualifications than the first rvalue.

An rvalue of type pointer to member of a class can be converted to an rvalue of type pointer to member of a class if the second rvalue contains more const or volatile qualifications than the first rvalue.

Function argument conversions

When a function is called, if a function declaration is present and includes declared argument types, the compiler performs type checking. The compiler compares the data types provided by the calling function with the data types that the called function expects and performs necessary type conversions. For example, when function funct is called, argument f is converted to a double, and argument c is converted to an int:

```c
char * funct (double d, int i);

int main(void){
  float f;
  char c;
  funct(f, c) /* f is converted to a double, c is converted to an int */
  return 0;
}
```

If no function declaration is visible when a function is called, or when an expression appears as an argument in the variable part of a prototype argument list, the compiler performs default argument promotions or converts the value of the expression before passing any arguments to the function. The automatic conversions consist of the following:

- The integral and floating-point promotions are performed.
- Arrays or functions are converted to pointers.
Chapter 6. Expressions and operators

Expressions are sequences of operators, operands, and punctuators that specify a computation. The evaluation of expressions is based on the operators that the expressions contain and the context in which they are used. An expression can result in a value and can produce side effects. A side effect is a change in the state of the execution environment.

“Operator precedence and associativity” on page 158 provides tables listing the precedence of all the operators described in the various sections listed above.

C++ operators can be defined to behave differently when applied to operands of class type. This is called operator overloading, and is described in “Overloading operators” on page 233.

Lvalues and rvalues

An object is a region of storage that can be examined and stored into. An lvalue is an expression that refers to such an object. An lvalue does not necessarily permit modification of the object it designates. For example, a const object is an lvalue that cannot be modified. The term modifiable lvalue is used to emphasize that the lvalue allows the designated object to be changed as well as examined. The following object types are lvalues, but not modifiable lvalues:

- An array type
- An incomplete type
- A const-qualified type
- A structure or union type with one of its members qualified as a const type

Because these lvalues are not modifiable, they cannot appear on the left side of an assignment statement.

The term rvalue refers to a data value that is stored at some address in memory. An rvalue is an expression that cannot have a value assigned to it. Both a literal constant and a variable can serve as an rvalue. When an lvalue appears in a context that requires an rvalue, the lvalue is implicitly converted to an rvalue. The reverse, however, is not true: an rvalue cannot be converted to an lvalue. Rvalues always have complete types or the void type.

C defines a function designator as an expression that has function type. A function designator is distinct from an object type or an lvalue. It can be the name of a function or the result of dereferencing a function pointer. The C language also differentiates between its treatment of a function pointer and an object pointer.

On the other hand, in C++, a function call that returns a reference is an lvalue. Otherwise, a function call is an rvalue expression. In C++, every expression produces an lvalue, an rvalue, or no value.

In both C and C++, certain operators require lvalues for some of their operands. The table below lists these operators and additional constraints on their usage.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Requirement</th>
</tr>
</thead>
<tbody>
<tr>
<td>&amp; (unary)</td>
<td>Operand must be an lvalue.</td>
</tr>
<tr>
<td>++ --</td>
<td>Operand must be an lvalue. This applies to both prefix and postfix forms.</td>
</tr>
<tr>
<td>= += -= *= %= &lt;&lt;= &gt;&gt;= &amp;= ^=</td>
<td>=</td>
</tr>
</tbody>
</table>
For example, all assignment operators evaluate their right operand and assign that value to their left operand. The left operand must be a modifiable lvalue or a reference to a modifiable object.

The address operator (&) requires an lvalue as an operand while the increment (++) and the decrement (--) operators require a modifiable lvalue as an operand. The following example shows expressions and their corresponding lvalues.

<table>
<thead>
<tr>
<th>Expression</th>
<th>Lvalue</th>
</tr>
</thead>
<tbody>
<tr>
<td>x = 42</td>
<td>x</td>
</tr>
<tr>
<td>*ptr = newvalue</td>
<td>*ptr</td>
</tr>
<tr>
<td>a++</td>
<td>a</td>
</tr>
<tr>
<td>int&amp; f()</td>
<td>The function call to f()</td>
</tr>
</tbody>
</table>

### Primary expressions

*Primary expressions* fall into the following general categories:

- Names (identifiers)
- Literals (constants)
- Integer constant expressions
- Identifier expressions
- Parenthesized expressions ( )
- The this pointer (described in “The this pointer” on page 261)
- Names qualified by the scope resolution operator (::)

### Names

The value of a name depends on its type, which is determined by how that name is declared. The following table shows whether a name is an lvalue expression.

| Name declared as          | Evaluates to                                                   | Is an lvalue? |
|---------------------------|----------------------------------------------------------------|
| Variable of arithmetic,   | An object of that type                                         | yes          |
| pointer, enumeration,     |                                                               |              |
| structure, or union type  |                                                               |              |
| Enumeration constant      | The associated integer value                                   | no           |
| Array                     | That array. In contexts subject to conversions, a pointer to   | no           |
|                           | the first object in the array, except where the name is used   |              |
|                           | as the argument to the sizeof operator.                        |              |
| Function                  | That function. In contexts subject to conversions, a pointer   | no           |
|                           | to that function, except where the name is used as the         |              |
|                           | argument to the sizeof operator, or as the function in a       |              |
|                           | function call expression.                                      |              |
As an expression, a name may not refer to a label, typedef name, structure member, union member, structure tag, union tag, or enumeration tag. Names used for these purposes reside in a namespace that is separate from that of names used in expressions. However, some of these names may be referred to within expressions by means of special constructs: for example, the dot or arrow operators may be used to refer to structure and union members; typedef names may be used in casts or as an argument to the sizeof operator.

### Literals

A literal is a numeric constant or string literal. When a literal is evaluated as an expression, its value is a constant. A lexical constant is never an lvalue. However, a string literal is an lvalue.

**Related reference**

- "Literals" on page 16
- "The this pointer" on page 261

### Integer constant expressions

An integer compile-time constant is a value that is determined during compilation and cannot be changed at run time. An integer compile-time constant expression is an expression that is composed of constants and evaluated to a constant.

An integer constant expression is an expression that is composed of only the following:
- literals
- enumerators
- const variables
- static data members of integral or enumeration types
- casts to integral types
- sizeof expressions, where the operand is not a variable length array

The sizeof operator applied to a variable length array type is evaluated at run time, and therefore is not a constant expression.

You must use an integer constant expression in the following situations:
- In the subscript declarator as the description of an array bound.
- After the keyword case in a switch statement.
- In an enumerator, as the numeric value of an enumeration constant.
- In a bit-field width specifier.
- In the preprocessor #if statement. (Enumeration constants, address constants, and sizeof cannot be specified in a preprocessor #if statement.)

**Related reference**

- "The sizeof operator" on page 128

### Identifier expressions (C++ only)

An identifier expression, or id-expression, is a restricted form of primary expression. Syntactically, an id-expression requires a higher level of complexity than a simple identifier to provide a name for all of the language elements of C++.
An *id-expression* can be either a qualified or unqualified identifier. It can also appear after the dot and arrow operators.

**Identifier expression syntax**

```
unqualified_id:
  identifier
  operator_function_id
  conversion_function_id
  ~
  class_name
  template_id
```

```
qualified_id:
  ::
  identifier
  operator_function_id
  template_id
  ::
  class_or_namespace::
  template
  ::
```

**Related reference**

- "Identifiers" on page 13
- Chapter 4, “Declarators,” on page 83

**Parenthesized expressions ( )**

Use parentheses to explicitly force the order of expression evaluation. The following expression does not use parentheses to group operands and operators. The parentheses surrounding `weight, zipcode` are used to form a function call. Note how the compiler groups the operands and operators in the expression according to the rules for operator precedence and associativity:

```
expression
  +
  *
  unary minus
  ~
  discount
  * item
  + handling ( weight, zipcode )
```

The following expression is similar to the previous expression, but it contains parentheses that change how the operands and operators are grouped:
In an expression that contains both associative and commutative operators, you can use parentheses to specify the grouping of operands with operators. The parentheses in the following expression guarantee the order of grouping operands with the operators:

\[ x = f + (g + h); \]

**Related reference**

“Operator precedence and associativity” on page 158

**Scope resolution operator :: (C++ only)**

The :: (scope resolution) operator is used to qualify hidden names so that you can still use them. You can use the unary scope operator if a namespace scope or global scope name is hidden by an explicit declaration of the same name in a block or class. For example:

```cpp
int count = 0;

int main(void) {
    int count = 0;
    ::count = 1; // set global count to 1
    count = 2;   // set local count to 2
    return 0;
}
```

The declaration of `count` declared in the `main` function hides the integer named `count` declared in global namespace scope. The statement `::count = 1` accesses the variable named `count` declared in global namespace scope.

You can also use the class scope operator to qualify class names or class member names. If a class member name is hidden, you can use it by qualifying it with its class name and the class scope operator.

In the following example, the declaration of the variable `X` hides the class type `X`, but you can still use the static class member `count` by qualifying it with the class type `X` and the scope resolution operator.
```cpp
#include <iostream>
using namespace std;

class X
{
public:
    static int count;
};

int X::count = 10; // define static data member

int main()
{
    int X = 0; // hides class type X
    cout << X::count << endl; // use static member of class X
}
```

### Function call expressions

A **function call** is an expression containing the function name followed by the function call operator, (). If the function has been defined to receive parameters, the values that are to be sent into the function are listed inside the parentheses of the function call operator. The argument list can contain any number of expressions separated by commas. The argument list can also be empty.

The type of a function call expression is the return type of the function. This type can either be a complete type, a reference type, or the type void. A function call expression is always an rvalue. A function call is an lvalue if and only if the type of the function is a reference.

Here are some examples of the function call operator:

```cpp
stub()
overdue(account, date, amount)
notify(name, date + 5)
report(error, time, date, ++num)
```

The order of evaluation for function call arguments is not specified. In the following example:

```cpp
method(sample1, batch.process--, batch.process);
```

the argument `batch.process--` might be evaluated last, causing the last two arguments to be passed with the same value.

### Member expressions

Member expressions indicate members of classes, structures, or unions. The member operators are:

- Dot operator `.`
- Arrow operator `->`

#### Dot operator `.`

The `. (dot)` operator is used to access class, structure, or union members. The member is specified by a postfix expression, followed by a `. (dot)` operator, followed by a possibly qualified identifier or a
pseudo-destructor name. (A pseudo-destructor is a destructor of a nonclass type.) The postfix expression must be an object of type class, struct or union. The name must be a member of that object.

The value of the expression is the value of the selected member. If the postfix expression and the name are lvalues, the expression value is also an lvalue. If the postfix expression is type-qualified, the same type qualifiers will apply to the designated member in the resulting expression.

Related reference
Access to structure and union members
“Pseudo-destructors” on page 316

Arrow operator ->

The -> (arrow) operator is used to access class, structure or union members using a pointer. A postfix expression, followed by an -> (arrow) operator, followed by a possibly qualified identifier or a pseudo-destructor name, designates a member of the object to which the pointer points. (A pseudo-destructor is a destructor of a nonclass type.) The postfix expression must be a pointer to an object of type class, struct or union. The name must be a member of that object.

The value of the expression is the value of the selected member. If the name is an lvalue, the expression value is also an lvalue. If the expression is a pointer to a qualified type, the same type-qualifiers will apply to the designated member in the resulting expression.

Related reference
“Pointers” on page 86
Access to structure and union members
“Structures and unions” on page 54
Chapter 12, “Class members and friends (C++ only),” on page 255
“Pseudo-destructors” on page 316

Unary expressions

A unary expression contains one operand and a unary operator.

The supported unary operators are:
• “Increment operator ++” on page 124
• “Decrement operator --” on page 124
• “Unary plus operator +” on page 125
• “Unary minus operator -” on page 125
• “Logical negation operator !” on page 125
• “Bitwise negation operator ~” on page 126
• “Address operator &” on page 126
• “Indirection operator *” on page 127
  • 
  • typeid
  • sizeof
  • IBM typeof
  • z/OS digitsof and precisionof
  • IBM __real__ and __imag__
All unary operators have the same precedence and have right-to-left associativity, as shown in Table 29 on page 159.

As indicated in the descriptions of the operators, the usual arithmetic conversions are performed on the operands of most unary expressions.

**Related reference**
- “Pointer arithmetic” on page 87
- “Lvalues and rvalues” on page 117
- “Arithmetic conversions and promotions” on page 107

**Increment operator ++**

The ++ (increment) operator adds 1 to the value of a scalar operand, or if the operand is a pointer, increments the operand by the size of the object to which it points. The operand receives the result of the increment operation. The operand must be a modifiable lvalue of arithmetic or pointer type.

You can put the ++ before or after the operand. If it appears before the operand, the operand is incremented. The incremented value is then used in the expression. If you put the ++ after the operand, the value of the operand is used in the expression before the operand is incremented. For example:

```
play = ++play1 + play2++;  
```

is similar to the following expressions; play2 is altered before play:

```
int temp, temp1, temp2;  
temp1 = play1 + 1;  
temp2 = play2;  
play1 = temp1;  
temp = temp1 + temp2;  
play2 = play2 + 1;  
play = temp;  
```

The result has the same type as the operand after integral promotion.

The usual arithmetic conversions on the operand are performed.

**Decrement operator --**

The -- (decrement) operator subtracts 1 from the value of a scalar operand, or if the operand is a pointer, decreases the operand by the size of the object to which it points. The operand receives the result of the decrement operation. The operand must be a modifiable lvalue.

You can put the -- before or after the operand. If it appears before the operand, the operand is decremented, and the decremented value is used in the expression. If the -- appears after the operand, the current value of the operand is used in the expression and the operand is decremented.

For example:

```
play = --play1 + play2--;  
```

is similar to the following expressions; play2 is altered before play:
The result has the same type as the operand after integral promotion, but is not an lvalue.

The usual arithmetic conversions are performed on the operand.

The decrement operator has been extended to handle complex types, for compatibility with GNU C. The operator works in the same manner as it does on a real type, except that only the real part of the operand is decremented, and the imaginary part is unchanged.

**Unary plus operator +**

The + (unary plus) operator maintains the value of the operand. The operand can have any arithmetic type or pointer type. The result is not an lvalue.

The result has the same type as the operand after integral promotion.

**Note:** Any plus sign in front of a constant is not part of the constant.

**Unary minus operator -**

The - (unary minus) operator negates the value of the operand. The operand can have any arithmetic type. The result is not an lvalue.

For example, if `quality` has the value 100, `-quality` has the value -100.

The result has the same type as the operand after integral promotion.

**Note:** Any minus sign in front of a constant is not part of the constant.

**Logical negation operator !**

The ! (logical negation) operator determines whether the operand evaluates to 0 (false) or nonzero (true).

The expression yields the value 1 (true) if the operand evaluates to 0, and yields the value 0 (false) if the operand evaluates to a nonzero value.

The expression yields the value true if the operand evaluates to false (0), and yields the value false if the operand evaluates to true (nonzero). The operand is implicitly converted to `bool`, and the type of the result is `bool`.

The following two expressions are equivalent:

```c
!right;
right == 0;
```
Bitwise negation operator ~

The ~ (bitwise negation) operator yields the bitwise complement of the operand. In the binary representation of the result, every bit has the opposite value of the same bit in the binary representation of the operand. The operand must have an integral type. The result has the same type as the operand but is not an lvalue.

Suppose \( x \) represents the decimal value 5. The 16-bit binary representation of \( x \) is:

\[
0000000000000101
\]

The expression \( \sim x \) yields the following result (represented here as a 16-bit binary number):

\[
1111111111111010
\]

Note that the \( \sim \) character can be represented by the trigraph ??-.

The 16-bit binary representation of \( \sim 0 \) is:

\[
1111111111111111
\]

The bitwise negation operator has been extended to handle complex types. With a complex type, the operator computes the complex conjugate of the operand by reversing the sign of the imaginary part.

Address operator &

The & (address) operator yields a pointer to its operand. The operand must be an lvalue, a function designator, or a qualified name. It cannot be a bit field, nor can it have the storage class register.

If the operand is an lvalue or function, the resulting type is a pointer to the expression type. For example, if the expression has type int, the result is a pointer to an object having type int.

If the operand is a qualified name and the member is not static, the result is a pointer to a member of class and has the same type as the member. The result is not an lvalue.

If \( p \_t o \_y \) is defined as a pointer to an int and \( y \) as an int, the following expression assigns the address of the variable \( y \) to the pointer \( p \_t o \_y \):

\[
p \_t o \_y = \&\_y;
\]

The ampersand symbol & is used in C++ as a reference declarator in addition to being the address operator. The meanings are related but not identical.

```c++
int target;
int &rTarg = target; // rTarg is a reference to an integer.
                  // The reference is initialized to refer to target.
void f(int*& p);   // p is a reference to a pointer
```

If you take the address of a reference, it returns the address of its target. Using the previous declarations, \( \&rTarg \) is the same memory address as \( \&target \).

You may take the address of a register variable.
You can use the & operator with overloaded functions only in an initialization or assignment where the left side uniquely determines which version of the overloaded function is used.

**Related reference**

"Indirection operator *"
"Pointers" on page 86
"References (C++ only)” on page 92

**Indirection operator ***

The * (indirection) operator determines the value referred to by the pointer-type operand. The operand cannot be a pointer to an incomplete type. If the operand points to an object, the operation yields an lvalue referring to that object. If the operand points to a function, the result is a function designator in C or, in C++, an lvalue referring to the object to which the operand points. Arrays and functions are converted to pointers.

The type of the operand determines the type of the result. For example, if the operand is a pointer to an int, the result has type int.

Do not apply the indirection operator to any pointer that contains an address that is not valid, such as NULL. The result is not defined.

If p_to_y is defined as a pointer to an int and y as an int, the expressions:

```cpp
p_to_y = &y;
*p_to_y = 3;
```

cause the variable y to receive the value 3.

"Arrays" on page 90
"Pointers" on page 86

**The typeid operator (C++ only)**

The typeid operator provides a program with the ability to retrieve the actual derived type of the object referred to by a pointer or a reference. This operator, along with the dynamic_cast operator, are provided for runtime type identification (RTTI) support in C++.

**typeid operator syntax**

```cpp
typeid(expr) -> type-name
```

The typeid operator returns an lvalue of type const std::type_info that represents the type of expression expr. You must include the standard template library header <typeinfo> to use the typeid operator.

If expr is a reference or a dereferenced pointer to a polymorphic class, typeid will return a type_info object that represents the object that the reference or pointer denotes at run time. If it is not a polymorphic class, typeid will return a type_info object that represents the type of the reference or dereferenced pointer. The following example demonstrates this:

```cpp
#include <iostream>
#include <typeinfo>
using namespace std;

struct A { virtual ^A() { } };
struct B : A { };
```
```c
struct C { };  
struct D : C { };  

int main() {  
  B bobj;  
  A* ap = &bobj;  
  A& ar = bobj;  
  cout << "ap: " << typeid(*ap).name() << endl;  
  cout << "ar: " << typeid(ar).name() << endl;  
  
  D dobj;  
  C* cp = &dobj;  
  C& cr = dobj;  
  cout << "cp: " << typeid(*cp).name() << endl;  
  cout << "cr: " << typeid(cr).name() << endl;  
}
```

The following is the output of the above example:

- `ap: B`
- `ar: B`
- `cp: C`
- `cr: C`

Classes A and B are polymorphic; classes C and D are not. Although cp and cr refer to an object of type D, typeid(*cp) and typeid(cr) return objects that represent class C.

Lvalue-to-value, array-to-pointer, and function-to-pointer conversions will not be applied to expr. For example, the output of the following example will be `int [10]`, not `int *`:

```c
#include <iostream>  
#include <typeinfo>  
using namespace std;  

int main() {  
  int myArray[10];  
  cout << typeid(myArray).name() << endl;  
}
```

If `expr` is a class type, that class must be completely defined.

The `typeid` operator ignores top-level `const` or `volatile` qualifiers.

### The sizeof operator

The `sizeof` operator yields the size in bytes of the operand, which can be an expression or the parenthesized name of a type.

**sizeof operator syntax**

```c
sizeof(expr)
```

The result for either kind of operand is not an lvalue, but a constant integer value. The type of the result is the unsigned integral type `size_t` defined in the header file `stddef.h`.

Except in preprocessor directives, you can use a `sizeof` expression wherever an integral constant is required. One of the most common uses for the `sizeof` operator is to determine the size of objects that are referred to during storage allocation, input, and output functions.
Another use of `sizeof` is in porting code across platforms. You can use the `sizeof` operator to determine the size that a data type represents. For example:

```c
sizeof(int);
```

The `sizeof` operator applied to a type name yields the amount of memory that can be used by an object of that type, including any internal or trailing padding.

Using the `sizeof` operator with a fixed-point decimal type results in the total number of bytes that are occupied by the decimal type. z/OS XL C/C++ implements decimal data types using the native packed decimal format. Each digit occupies half a byte. The sign occupies an additional half byte. The following example gives you a result of 6 bytes:

```c
sizeof(decimal(10,2));
```

For compound types, results are as follows:

<table>
<thead>
<tr>
<th>Operand</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>An array</td>
<td>The result is the total number of bytes in the array. For example, in an array with 10 elements, the size is equal to 10 times the size of a single element. The compiler does not convert the array to a pointer before evaluating the expression.</td>
</tr>
<tr>
<td>A class</td>
<td>The result is always nonzero. It is equal to the number of bytes in an object of that class, also including any padding required for placing class objects in an array.</td>
</tr>
<tr>
<td>A reference</td>
<td>The result is the size of the referenced object.</td>
</tr>
</tbody>
</table>

The `sizeof` operator cannot be applied to:
- A bit field
- A function type
- An undefined structure or class
- An incomplete type (such as `void`)

The `sizeof` operator applied to an expression yields the same result as if it had been applied to only the name of the type of the expression. At compile time, the compiler analyzes the expression to determine its type. None of the usual type conversions that occur in the type analysis of the expression are directly attributable to the `sizeof` operator. However, if the operand contains operators that perform conversions, the compiler does take these conversions into consideration in determining the type. For example, the second line of the following sample causes the usual arithmetic conversions to be performed. Assuming that a short uses 2 bytes of storage and an int uses 4 bytes,

```c
short x; ... sizeof (x)  /* the value of sizeof operator is 2 */
short x; ... sizeof (x + 1)  /* value is 4, result of addition is type int */
```

The result of the expression `x + 1` has type `int` and is equivalent to `sizeof(int)`. The value is also 4 if `x` has type `char`, `short`, or `int` or any enumeration type.

`sizeof...` is a unary expression operator introduced by the variadic template feature. This operator accepts an expression that names a parameter pack as its operand. It then expands the parameter pack and returns the number of arguments provided for the parameter pack. Consider the following example:

```c
template<typename...T> void foo(T...args){
    int v = sizeof...(args);
}
```
In this example, the variable \( v \) is assigned to the number of the arguments provided for the parameter pack args.

**Notes:**
- The operand of the `sizeof...` operator must be an expression that names a parameter pack.
- The operand of the `sizeof` operator cannot be an expression that names a parameter pack or a pack expansion.

For more information, see "Variadic templates (C++0x)" on page 356

**The typeof operator (IBM extension)**

The `typeof` operator returns the type of its argument, which can be an expression or a type. The language feature provides a way to derive the type from an expression. Given an expression `e`, `__typeof__(e)` can be used anywhere a type name is needed, for example in a declaration or in a cast. The alternate spelling of the keyword, `__typeof__`, is recommended.

**typeof operator syntax**

```
typeof(expr) type-name
```

A `typeof` construct itself is not an expression, but the name of a type. A `typeof` construct behaves like a type name defined using `typedef`, although the syntax resembles that of `sizeof`.

The following examples illustrate its basic syntax. For an expression `e`:

```c
int e;
__typeof__(e + 1) j; /* the same as declaring int j; */
e = (__typeof__(e)) f; /* the same as casting e = (int) f; */
```

Using a `typeof` construct is equivalent to declaring a `typedef` name. Given

```c
int T[2];
int i[2];
```

you can write

```c
__typeof__(i) a;      /* all three constructs have the same meaning */
__typeof__(int[2]) a;
__typeof__(T) a;
```

The behavior of the code is as if you had declared `int a[2];`.

For a bit field, `typeof` represents the underlying type of the bit field. For example, `int n:2;`, the `typeof(m)` is `int`. Since the bit field property is not reserved, `n` in `typeof(m) n;` is the same as `int n`, but not `int n:2`.

The `typeof` operator can be nested inside `sizeof` and itself. The following declarations of `arr` as an array of pointers to `int` are equivalent:

```c
int *arr[10];      /* traditional C declaration */
__typeof__(__typeof__(int *)[10]) a; /* equivalent declaration */
```

The `typeof` operator can be useful in macro definitions where expression \( e \) is a parameter. For example,
#define SWAP(a,b) { __typeof__(a) temp; temp = a; a = b; b = temp; }

Note:
1. The typeof and __typeof__ keywords are supported as follows:
   • The __typeof__ keyword is recognized in C under LANGLVL(EXTC89| EXTC99|EXTENDED),
     and in C++ under the LANGLVL(EXTENDED).
   • The typeof keyword is only recognized when the KEYWORD(TYPEOF) compiler option is in
     effect.

The digitsof and precisionof operators (C only)

The digitsof and precisionof operators yield information about fixed-point decimal types or an
expressions of the decimal type. The decimal.h header file defines the digitsof and precisionof macros.

The digitsof operator gives the number of significant digits of an object, and precisionof gives the
number of decimal digits. That is,

digitsof(decimal(n,p)) = n
precisionof(decimal(n,p)) = p

The results of the digitsof and precisionof operators are integer constants.

Fixed-point decimal literals (z/OS only)
"Fixed point decimal types (C only)" on page 52

The __real__ and __imag__ operators

z/OS XL C/C++ extends the C99 standards to support the unary operators __real__ and __imag__. These
operators provide the ability to extract the real and imaginary parts of a complex type. These extensions
have been implemented to ease the porting applications developed with GNU C.

__real__ and __imag__ operator syntax

```
__real__(--var_identifier--)
__imag__(--var_identifier--)
```

The var_identifier is the name of a previously declared complex variable. The __real__ operator returns
the real part of the complex variable, while the __imag__ operator returns the imaginary part of the
variable. If the operand of these operators is an lvalue, the resulting expression can be used in any
context where lvalues are allowed. They are especially useful in initializations of complex variables, and as
arguments to calls to library functions such as printf and scanf that have no format specifiers for complex
types. For example:

```c
float _Complex myvar;
__imag__(myvar) = 2.0f;
__real__(myvar) = 3.0f;
```

initializes the imaginary part of the complex variable myvar to 2.0i and the real part to 3.0, and

```c
printf("myvar = %f + %f * i\n", __real__(myvar), __imag__(myvar));
```

prints:
```
myvar = 2.000000 + 3.000000 * i
```

Binary expressions

A binary expression contains two operands separated by one operator. The supported binary operators are:

- Assignment operators
- Multiplication operator `*` on page 134
- Division operator `/` on page 135
- Remainder operator `%` on page 135
- Addition operator `+` on page 135
- Subtraction operator `-` on page 135
- Bitwise left and right shift operators `<< >>` on page 136
- Relational operators `< > <= => =` on page 136
- Equality and inequality operators `== !=` on page 137
- Bitwise AND operator `&` on page 138
- Bitwise exclusive OR operator `^` on page 139
- Bitwise inclusive OR operator `|` on page 139
- Logical AND operator `&&` on page 140
- Logical OR operator `||` on page 140
- Array subscripting operator `[]` on page 141
- Comma operator `,` on page 142
- Pointer to member operators `.* -> *` (C++ only) on page 144

All binary operators have left-to-right associativity, but not all binary operators have the same precedence. The ranking and precedence rules for binary operators is summarized in Table 30 on page 160.

The order in which the operands of most binary operators are evaluated is not specified. To ensure correct results, avoid creating binary expressions that depend on the order in which the compiler evaluates the operands.

As indicated in the descriptions of the operators, the usual arithmetic conversions are performed on the operands of most binary expressions.

- Arithmetic conversions and promotions on page 107

Assignment operators

An assignment expression stores a value in the object designated by the left operand. There are two types of assignment operators:

- Simple assignment operator `=` on page 133
- Compound assignment operators on page 133

The left operand in all assignment expressions must be a modifiable lvalue. The type of the expression is the type of the left operand. The value of the expression is the value of the left operand after the assignment has completed.
The result of an assignment expression is not an lvalue. The result of an assignment expression is an lvalue.

All assignment operators have the same precedence and have right-to-left associativity.

**Simple assignment operator =**

The simple assignment operator has the following form:

```
  lvalue = expr
```

The operator stores the value of the right operand `expr` in the object designated by the left operand `lvalue`.

The left operand must be a modifiable lvalue. The type of an assignment operation is the type of the left operand.

If the left operand is not a class type, the right operand is implicitly converted to the type of the left operand. This converted type will not be qualified by `const` or `volatile`.

If the left operand is a class type, that type must be complete. The copy assignment operator of the left operand will be called.

If the left operand is an object of reference type, the compiler will assign the value of the right operand to the object denoted by the reference.

A packed structure or union can be assigned to a nonpacked structure or union of the same type. A nonpacked structure or union can be assigned to a packed structure or union of the same type.

If one operand is packed and the other is not, z/OS XL C/C++ remaps the layout of the right operand to match the layout of the left. This remapping of structures might degrade performance. For efficiency, when you perform assignment operations with structures or unions, you should ensure that both operands are either packed or nonpacked.

**Note:** If you assign pointers to structures or unions, the objects they point to must both be either packed or nonpacked. See "Initialization of pointers" on page 100 for more information on assignments with pointers.

**Compound assignment operators**

The compound assignment operators consist of a binary operator and the simple assignment operator. They perform the operation of the binary operator on both operands and store the result of that operation into the left operand, which must be a modifiable lvalue.

The following table shows the operand types of compound assignment expressions:

<table>
<thead>
<tr>
<th>Operator</th>
<th>Left operand</th>
<th>Right operand</th>
</tr>
</thead>
<tbody>
<tr>
<td>+= or -=</td>
<td>Arithmetic</td>
<td>Arithmetic</td>
</tr>
<tr>
<td>+= or -=</td>
<td>Pointer</td>
<td>Integral type</td>
</tr>
<tr>
<td>*=, /=, and %=</td>
<td>Arithmetic</td>
<td>Arithmetic</td>
</tr>
<tr>
<td>&lt;&lt;=, &gt;&gt;=, &amp;=, ^=, and</td>
<td>=</td>
<td>Integral type</td>
</tr>
</tbody>
</table>

Note that the expression

```
a *= b + c
```
is equivalent to
\[ a = a \times (b + c) \]

and not
\[ a = a \times b + c \]

The following table lists the compound assignment operators and shows an expression using each operator:

<table>
<thead>
<tr>
<th>Operator</th>
<th>Example</th>
<th>Equivalent expression</th>
</tr>
</thead>
<tbody>
<tr>
<td>+=</td>
<td>index += 2</td>
<td>index = index + 2</td>
</tr>
<tr>
<td>-=</td>
<td>*(pointer++) -= 1</td>
<td>*pointer = *(pointer++) - 1</td>
</tr>
<tr>
<td>*=</td>
<td>bonus ** increase</td>
<td>bonus = bonus \times increase</td>
</tr>
<tr>
<td>/=</td>
<td>time /= hours</td>
<td>time = time / hours</td>
</tr>
<tr>
<td>%=</td>
<td>allowance %= 1000</td>
<td>allowance = allowance % 1000</td>
</tr>
<tr>
<td>&lt;&lt;=</td>
<td>result &lt;&lt;= num</td>
<td>result = result &lt;&lt; num</td>
</tr>
<tr>
<td>&gt;&gt;=</td>
<td>form &gt;&gt;= 1</td>
<td>form = form &gt;&gt; 1</td>
</tr>
<tr>
<td>&amp;=</td>
<td>mask &amp;= 2</td>
<td>mask = mask &amp; 2</td>
</tr>
<tr>
<td>^=</td>
<td>test ^= pre_test</td>
<td>test = test ^ pre_test</td>
</tr>
<tr>
<td></td>
<td>=</td>
<td>flag</td>
</tr>
</tbody>
</table>

Although the equivalent expression column shows the left operands (from the example column) twice, it is in effect evaluated only once.

In addition to the table of operand types, an expression is implicitly converted to the cv-unqualified type of the left operand if it is not of class type. However, if the left operand is of class type, the class becomes complete, and assignment to objects of the class behaves as a copy assignment operation. Compound expressions and conditional expressions are lvalues in C++, which allows them to be a left operand in a compound assignment expression.

"Lvalues and rvalues" on page 117
"Pointers" on page 86
"Type qualifiers" on page 74

**Multiplication operator * **

The \( \times \) (multiplication) operator yields the product of its operands. The operands must have an arithmetic or enumeration type. The result is not an lvalue. The usual arithmetic conversions on the operands are performed.

Because the multiplication operator has both associative and commutative properties, the compiler can rearrange the operands in an expression that contains more than one multiplication operator. For example, the expression:
\[ \text{sites} \times \text{number} \times \text{cost} \]
can be interpreted in any of the following ways:
\[ (\text{sites} \times \text{number}) \times \text{cost} \]
\[ \text{sites} \times (\text{number} \times \text{cost}) \]
\[ (\text{cost} \times \text{sites}) \times \text{number} \]
Division operator /

The / (division) operator yields the algebraic quotient of its operands. If both operands are integers, any fractional part (remainder) is discarded. Throwing away the fractional part is often called truncation toward zero. The operands must have an arithmetic or enumeration type. The right operand may not be zero: the result is undefined if the right operand evaluates to 0. For example, expression 7 / 4 yields the value 1 (rather than 1.75 or 2). The result is not an lvalue.

If either operand is negative, the result is rounded towards zero.

The usual arithmetic conversions on the operands are performed.

Remainder operator %

The % (remainder) operator yields the remainder from the division of the left operand by the right operand. For example, the expression 5 % 3 yields 2. The result is not an lvalue.

Both operands must have an integral or enumeration type. If the right operand evaluates to 0, the result is undefined. If either operand has a negative value, the result is such that the following expression always yields the value of a if b is not 0 and a/b is representable:

\[(a / b) * b + a \% b;\]

The usual arithmetic conversions on the operands are performed.

Addition operator +

The + (addition) operator yields the sum of its operands. Both operands must have an arithmetic type, or one operand must be a pointer to an object type and the other operand must have an integral or enumeration type.

When both operands have an arithmetic type, the usual arithmetic conversions on the operands are performed. The result has the type produced by the conversions on the operands and is not an lvalue.

A pointer to an object in an array can be added to a value having integral type. The result is a pointer of the same type as the pointer operand. The result refers to another element in the array, offset from the original element by the amount of the integral value treated as a subscript. If the resulting pointer points to storage outside the array, other than the first location outside the array, the result is undefined. A pointer to one element past the end of an array cannot be used to access the memory content at that address. The compiler does not provide boundary checking on the pointers. For example, after the addition, ptr points to the third element of the array:

```c
int array[5];
int *ptr;
ptr = array + 2;
```

Related reference

"Pointer arithmetic" on page 87
"Pointer conversions" on page 114

Subtraction operator -

The - (subtraction) operator yields the difference of its operands. Both operands must have an arithmetic or enumeration type, or the left operand must have a pointer type and the right operand must have the same pointer type or an integral or enumeration type. You cannot subtract a pointer from an integral value.
When both operands have an arithmetic type, the usual arithmetic conversions on the operands are performed. The result has the type produced by the conversions on the operands and is not an lvalue.

When the left operand is a pointer and the right operand has an integral type, the compiler converts the value of the right to an address offset. The result is a pointer of the same type as the pointer operand.

If both operands are pointers to elements in the same array, the result is the number of objects separating the two addresses. The number is of type ptrdiff_t, which is defined in the header file stddef.h. Behavior is undefined if the pointers do not refer to objects in the same array.

Related reference
“Pointer arithmetic” on page 87
“Pointer conversions” on page 114

Bitwise left and right shift operators << >>

The bitwise shift operators move the bit values of a binary object. The left operand specifies the value to be shifted. The right operand specifies the number of positions that the bits in the value are to be shifted. The result is not an lvalue. Both operands have the same precedence and are left-to-right associative.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;&lt;</td>
<td>Indicates the bits are to be shifted to the left.</td>
</tr>
<tr>
<td>&gt;&gt;</td>
<td>Indicates the bits are to be shifted to the right.</td>
</tr>
</tbody>
</table>

Each operand must have an integral or enumeration type. The compiler performs integral promotions on the operands, and then the right operand is converted to type int. The result has the same type as the left operand (after the arithmetic conversions).

The right operand should not have a negative value or a value that is greater than or equal to the width in bits of the expression being shifted. The result of bitwise shifts on such values is unpredictable.

If the right operand has the value 0, the result is the value of the left operand (after the usual arithmetic conversions).

The << operator fills vacated bits with zeros. For example, if left_op has the value 4019, the bit pattern (in 16-bit format) of left_op is:
0000111110110011

The expression left_op << 3 yields:
0111110110011000

The expression left_op >> 3 yields:
0000001111101110

Relational operators < > <= >=

The relational operators compare two operands and determine the validity of a relationship. The following table describes the four relational operators:

<table>
<thead>
<tr>
<th>Operator</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;</td>
<td>Indicates whether the value of the left operand is less than the value of the right operand.</td>
</tr>
</tbody>
</table>
Both operands must have arithmetic or enumeration types or be pointers to the same type.

<table>
<thead>
<tr>
<th>Operator</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>&gt;</td>
<td>Indicates whether the value of the left operand is greater than the value of the right operand.</td>
</tr>
<tr>
<td>&lt;=</td>
<td>Indicates whether the value of the left operand is less than or equal to the value of the right operand.</td>
</tr>
<tr>
<td>&gt;=</td>
<td>Indicates whether the value of the left operand is greater than or equal to the value of the right operand.</td>
</tr>
</tbody>
</table>

The result is not an lvalue.

If the operands have arithmetic types, the usual arithmetic conversions on the operands are performed.

When the operands are pointers, the result is determined by the locations of the objects to which the pointers refer. If the pointers do not refer to objects in the same array, the result is not defined.

A pointer can be compared to a constant expression that evaluates to 0. You can also compare a pointer to a pointer of type void*. The pointer is converted to a pointer of type void*.

If two pointers refer to the same object, they are considered equal. If two pointers refer to nonstatic members of the same object, the pointer to the object declared later is greater, provided that they are not separated by an access specifier; otherwise the comparison is undefined. If two pointers refer to data members of the same union, they have the same address value.

If two pointers refer to elements of the same array, or to the first element beyond the last element of an array, the pointer to the element with the higher subscript value is greater.

You can only compare members of the same object with relational operators.

Relational operators have left-to-right associativity. For example, the expression:

\[ a < b <= c \]

is interpreted as:

\[(a < b) <= c\]

If the value of \(a\) is less than the value of \(b\), the first relationship yields 1 in C, or true in C++. The compiler then compares the value true (or 1) with the value of \(c\) (integral promotions are carried out if needed).

**Equality and inequality operators == !=**

The equality operators, like the relational operators, compare two operands for the validity of a relationship. The equality operators, however, have a lower precedence than the relational operators. The following table describes the two equality operators:

<table>
<thead>
<tr>
<th>Operator</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>==</td>
<td>Indicates whether the value of the left operand is equal to the value of the right operand.</td>
</tr>
</tbody>
</table>
Operator | Usage
--- | ---
!= | Indicates whether the value of the left operand is not equal to the value of the right operand.

Both operands must have arithmetic or enumeration types or be pointers to the same type, or one operand must have a pointer type and the other operand must be a pointer to void or a null pointer.

C The type of the result is int and has the values 1 if the specified relationship is true, and 0 if false. C++ The type of the result is bool and has the values true or false.

If the operands have arithmetic types, the usual arithmetic conversions on the operands are performed.

If the operands are pointers, the result is determined by the locations of the objects to which the pointers refer.

If one operand is a pointer and the other operand is an integer having the value 0, the == expression is true only if the pointer operand evaluates to NULL. The != operator evaluates to true if the pointer operand does not evaluate to NULL.

You can also use the equality operators to compare pointers to members that are of the same type but do not belong to the same object. The following expressions contain examples of equality and relational operators:

\[
\text{time < max\_time == status < complete} \\
\text{letter != EOF}
\]

**Note:** The equality operator (==) should not be confused with the assignment (=) operator.

For example,

\[
\text{if (x == 3)}
\]

- evaluates to true (or 1) if x is equal to three. Equality tests like this should be coded with spaces between the operator and the operands to prevent unintentional assignments.

  while

- if (x = 3)

  is taken to be true because \((x = 3)\) evaluates to a nonzero value (3). The expression also assigns the value 3 to x.

**Simple assignment operator** =

**Bitwise AND operator &**

The & (bitwise AND) operator compares each bit of its first operand to the corresponding bit of the second operand. If both bits are 1's, the corresponding bit of the result is set to 1. Otherwise, it sets the corresponding result bit to 0.

Both operands must have an integral or enumeration type. The usual arithmetic conversions on each operand are performed. The result has the same type as the converted operands.

Because the bitwise AND operator has both associative and commutative properties, the compiler can rearrange the operands in an expression that contains more than one bitwise AND operator.

The following example shows the values of a, b, and the result of a & b represented as 16-bit binary numbers:
bit pattern of a 0000000001011100
bit pattern of b 0000000001011100
bit pattern of a & b 0000000000001100

Note: The bitwise AND (\&) should not be confused with the logical AND (&&) operator. For example,

\[
\begin{align*}
1 & 4 & \text{evaluates to 0} \\
\text{while} & \\
1 & \& & 4 & \text{evaluates to true}
\end{align*}
\]

**Bitwise exclusive OR operator ^**

The bitwise exclusive OR operator (in EBCDIC, the ^ symbol is represented by the ¬ symbol) compares each bit of its first operand to the corresponding bit of the second operand. If both bits are 1's or both bits are 0's, the corresponding bit of the result is set to 0. Otherwise, it sets the corresponding result bit to 1.

Both operands must have an integral or enumeration type. The usual arithmetic conversions on each operand are performed. The result has the same type as the converted operands and is not an lvalue.

Because the bitwise exclusive OR operator has both associative and commutative properties, the compiler can rearrange the operands in an expression that contains more than one bitwise exclusive OR operator. Note that the ^ character can be represented by the trigraph ??'.

The following example shows the values of a, b, and the result of a ^ b represented as 16-bit binary numbers:

<table>
<thead>
<tr>
<th>bit pattern of a</th>
<th>0000000001011100</th>
</tr>
</thead>
<tbody>
<tr>
<td>bit pattern of b</td>
<td>0000000001011100</td>
</tr>
<tr>
<td>bit pattern of a ^ b</td>
<td>0000000001110010</td>
</tr>
</tbody>
</table>

**Related reference**

"Trigraph sequences" on page 34

**Bitwise inclusive OR operator |**

The | (bitwise inclusive OR) operator compares the values (in binary format) of each operand and yields a value whose bit pattern shows which bits in either of the operands has the value 1. If both of the bits are 0, the result of that bit is 0; otherwise, the result is 1.

Both operands must have an integral or enumeration type. The usual arithmetic conversions on each operand are performed. The result has the same type as the converted operands and is not an lvalue.

Because the bitwise inclusive OR operator has both associative and commutative properties, the compiler can rearrange the operands in an expression that contains more than one bitwise inclusive OR operator. Note that the | character can be represented by the trigraph ??!.

The following example shows the values of a, b, and the result of a | b represented as 16-bit binary numbers:

<table>
<thead>
<tr>
<th>bit pattern of a</th>
<th>0000000001011100</th>
</tr>
</thead>
<tbody>
<tr>
<td>bit pattern of b</td>
<td>0000000001011100</td>
</tr>
<tr>
<td>bit pattern of a</td>
<td>b</td>
</tr>
</tbody>
</table>
Note: The bitwise OR (|) should not be confused with the logical OR (||) operator. For example,

\[
1 | 4 \text{ evaluates to } 5 \\
\text{while} \\
1 || 4 \text{ evaluates to true}
\]

Related reference
“Trigraph sequences” on page 34

Logical AND operator &&

The && (logical AND) operator indicates whether both operands are true.

- C If both operands have nonzero values, the result has the value 1. Otherwise, the result has the value 0. The type of the result is int. Both operands must have a arithmetic or pointer type. The usual arithmetic conversions on each operand are performed.

- C++ If both operands have values of true, the result has the value true. Otherwise, the result has the value false. Both operands are implicitly converted to bool and the result type is bool.

Unlike the & (bitwise AND) operator, the && operator guarantees left-to-right evaluation of the operands. If the left operand evaluates to 0 (or false), the right operand is not evaluated.

The following examples show how the expressions that contain the logical AND operator are evaluated:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 &amp;&amp; 0</td>
<td>false or 0</td>
</tr>
<tr>
<td>1 &amp;&amp; 4</td>
<td>true or 1</td>
</tr>
<tr>
<td>0 &amp;&amp; 0</td>
<td>false or 0</td>
</tr>
</tbody>
</table>

The following example uses the logical AND operator to avoid division by zero:

\[(y != 0) && (x / y)\]

The expression \[x / y\] is not evaluated when \[y != 0\] evaluates to 0 (or false).

Note: The logical AND (&&) should not be confused with the bitwise AND (&) operator. For example:

\[
1 && 4 \text{ evaluates to } 1 \text{ (or true)} \\
\text{while} \\
1 & 4 \text{ evaluates to } 0
\]

Logical OR operator ||

The || (logical OR) operator indicates whether either operand is true.

- C If either of the operands has a nonzero value, the result has the value 1. Otherwise, the result has the value 0. The type of the result is int. Both operands must have a arithmetic or pointer type. The usual arithmetic conversions on each operand are performed.

- C++ If either operand has a value of true, the result has the value true. Otherwise, the result has the value false. Both operands are implicitly converted to bool and the result type is bool.
Unlike the | (bitwise inclusive OR) operator, the || operator guarantees left-to-right evaluation of the operands. If the left operand has a nonzero (or true) value, the right operand is not evaluated.

The following examples show how expressions that contain the logical OR operator are evaluated:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td></td>
</tr>
<tr>
<td>1</td>
<td></td>
</tr>
<tr>
<td>0</td>
<td></td>
</tr>
</tbody>
</table>

The following example uses the logical OR operator to conditionally increment y:

```
++x || ++y;
```

The expression ++y is not evaluated when the expression ++x evaluates to a nonzero (or true) quantity.

**Note:** The logical OR (||) should not be confused with the bitwise OR (|) operator. For example:

```
1 | 4 evaluates to 1 (or true)
   while 1 || 4 evaluates to 5
```

**Array subscripting operator [ ]**

A postfix expression followed by an expression in [ ] (brackets) specifies an element of an array. The expression within the brackets is referred to as a subscript. The first element of an array has the subscript zero.

By definition, the expression a[b] is equivalent to the expression *((a) + (b)), and, because addition is associative, it is also equivalent to b[a]. Between expressions a and b, one must be a pointer to a type T, and the other must have integral or enumeration type. The result of an array subscript is an lvalue. The following example demonstrates this:

```
#include <stdio.h>

int main(void) {
    int a[3] = { 10, 20, 30 };
    printf("a[0] = %d\n", a[0]);
    printf("a[1] = %d\n", 1[a]);
    printf("a[2] = %d\n", *(2 + a));
    return 0;
}
```

The following is the output of the above example:

```
a[0] = 10
a[1] = 20
a[2] = 30
```

The above restrictions on the types of expressions required by the subscript operator, as well as the relationship between the subscript operator and pointer arithmetic, do not apply if you overload operator[] of a class.

The first element of each array has the subscript 0. The expression `contract[35]` refers to the 36th element in the array `contract`.

In a multidimensional array, you can reference each element (in the order of increasing storage locations) by incrementing the right-most subscript most frequently.
For example, the following statement gives the value 100 to each element in the array `code[4][3][6]`:

```c
for (first = 0; first < 4; ++first)
{
    for (second = 0; second < 3; ++second)
    {
        for (third = 0; third < 6; ++third)
        {
            code[first][second][third] = 100;
        }
    }
}
```

C99 allows array subscripting on arrays that are not lvalues. However, using the address of a non-lvalue as an array subscript is still not allowed. The following example is valid in C99:

```c
struct trio{int a[3];};
struct trio f();
foo (int index)
{
    return f().a[index];
}
```

**Vector subscripting operator [ ] (IBM extension)**

Access to individual elements of a vector data type is provided through the use of square brackets, similar to how array elements are accessed. The vector data type is followed by a set of square brackets containing the position of the element. The position of the first element is 0. The type of the result is the type of the elements contained in the vector type.

Example:

```c
vector unsigned int v1 = {1,2,3,4};
unsigned int u1, u2, u3, u4;
u1 = v1[0]; // u1=1
u2 = v1[1]; // u2=2
u3 = v1[2]; // u3=3
u4 = v1[3]; // u4=4
```

**Note:** You can also access and manipulate individual elements of vectors with the following intrinsic functions:

- `vec_extract`
- `vec_insert`
- `vec_promote`
- `vec_splats`

**Comma operator ,**

A *comma expression* contains two operands of any type separated by a comma and has left-to-right associativity. The left operand is fully evaluated, possibly producing side effects, and its value, if there is
The result of a comma expression is not an lvalue.

In C++, the result is an lvalue if the right operand is an lvalue. The following statements are equivalent:

```c
r = (a,b,...,c);
a; b; r = c;
```

The difference is that the comma operator may be suitable for expression contexts, such as loop control expressions.

Similarly, the address of a compound expression can be taken if the right operand is an lvalue.

```c
&(a, b)
a, &b
```

Any number of expressions separated by commas can form a single expression because the comma operator is associative. The use of the comma operator guarantees that the subexpressions will be evaluated in left-to-right order, and the value of the last becomes the value of the entire expression. In the following example, if omega has the value 11, the expression increments delta and assigns the value 3 to alpha:

```c
alpha = (delta++, omega % 4);
```

A sequence point occurs after the evaluation of the first operand. The value of delta is discarded. Similarly, in the following example, the value of the expression:

```c
intensity++, shade * increment, rotate(direction);
```

is the value of the expression:

```c
rotate(direction)
```

In some contexts where the comma character is used, parentheses are required to avoid ambiguity. For example, the function

```c
f(a, (t = 3, t + 2), c);
```

has only three arguments: the value of a, the value 5, and the value of c. Other contexts in which parentheses are required are in field-length expressions in structure and union declarator lists, enumeration value expressions in enumeration declarator lists, and initialization expressions in declarations and initializers.

In the previous example, the comma is used to separate the argument expressions in a function invocation. In this context, its use does not guarantee the order of evaluation (left to right) of the function arguments.

The primary use of the comma operator is to produce side effects in the following situations:

- Calling a function
- Entering or repeating an iteration loop
- Testing a condition
- Other situations where a side effect is required but the result of the expression is not immediately needed

The following table gives some examples of the uses of the comma operator.
Statement | Effects
--- | ---
for (i=0; i<2; ++i, f() ); | A for statement in which i is incremented and f() is called at each iteration.
if ( f(), ++i, i>1 ) { /* ... */ } | An if statement in which function f() is called, variable i is incremented, and variable i is tested against a value. The first two expressions within this comma expression are evaluated before the expression i>1. Regardless of the results of the first two expressions, the third is evaluated and its result determines whether the if statement is processed.
func( ( ++a, f(a) ) ); | A function call to func() in which a is incremented, the resulting value is passed to a function f(), and the return value of f() is passed to func(). The function func() is passed only a single argument, because the comma expression is enclosed in parentheses within the function argument list.

**Pointer to member operators .* - >* (C++ only)**

There are two pointer to member operators: .* and ->*.

The .* operator is used to dereference pointers to class members. The first operand must be of class type. If the type of the first operand is class type T1, or is a class that has been derived from class type T1, the second operand must be a pointer to a member of a class type T1.

The ->* operator is also used to dereference pointers to class members. The first operand must be a pointer to a class type. If the type of the first operand is a pointer to class type T1, or is a pointer to a class derived from class type T1, the second operand must be a pointer to a member of class type T1.

The .* and ->* operators bind the second operand to the first, resulting in an object or function of the type specified by the second operand.

If the result of .* or ->* is a function, you can only use the result as the operand for the ( ) (function call) operator. If the second operand is an lvalue, the result of .* or ->* is an lvalue.

**Related reference**
- “Class member lists” on page 255
- “Pointers to members” on page 260

**Conditional expressions**

A conditional expression is a compound expression that contains a condition that is implicitly converted to type bool in C++(operand1), an expression to be evaluated if the condition evaluates to true (operand2), and an expression to be evaluated if the condition has the value false (operand3).

The conditional expression contains one two-part operator. The ? symbol follows the condition, and the : symbol appears between the two action expressions. All expressions that occur between the ? and : are treated as one expression.

The first operand must have a scalar type. The type of the second and third operands must be one of the following:
- An arithmetic type
- A compatible pointer, structure, or union type
- void

The second and third operands can also be a pointer or a null pointer constant.
Two objects are compatible when they have the same type but not necessarily the same type qualifiers (volatile or const). Pointer objects are compatible if they have the same type or are pointers to void.

The first operand is evaluated, and its value determines whether the second or third operand is evaluated:
- If the value is true, the second operand is evaluated.
- If the value is false, the third operand is evaluated.

The result is the value of the second or third operand.

If the second and third expressions evaluate to arithmetic types, the usual arithmetic conversions are performed on the values. The types of the second and third operands determine the type of the result as shown in the following tables.

Conditional expressions have right-to-left associativity with respect to their first and third operands. The leftmost operand is evaluated first, and then only one of the remaining two operands is evaluated. The following expressions are equivalent:

\[
a \ ? \ b \ : \ c \ ? \ d \ : \ e \ ? \ f \ : \ g
a \ ? \ b \ : \ (c \ ? \ d \ : \ (e \ ? \ f \ : \ g))
\]

**Types in conditional C expressions (C only)**

In C, a conditional expression is not an lvalue, nor is its result.

*Table 26. Types of operands and results in conditional C expressions*

</tbody>
</table>
Examples of conditional expressions

The following expression determines which variable has the greater value, \(y\) or \(z\), and assigns the greater value to the variable \(x\):

\[
x = (y > z) \ ? \ y : z;
\]

The following is an equivalent statement:

\[
\text{if} \ (y > z) \\
\quad x = y; \\
\text{else} \\
\quad x = z;
\]

The following expression calls the function `printf`, which receives the value of the variable \(c\), if \(c\) evaluates to a digit. Otherwise, `printf` receives the character constant `'x'`.

\[
\text{printf}(" c = %c\n", \text{isdigit}(c) \ ? \ c : 'x');
\]

If the last operand of a conditional expression contains an assignment operator, use parentheses to ensure the expression evaluates properly. For example, the `=` operator has higher precedence than the `?:` operator in the following expression:

\[
\text{int} \ i,j,k; \\
(i == 7) \ ? \ j ++ : k = j;
\]

The compiler will interpret this expression as if it were parenthesized this way:

\[
\text{int} \ i,j,k; \\
((i == 7) \ ? \ j ++ : k) = j;
\]

That is, \(k\) is treated as the third operand, not the entire assignment expression \(k = j\).

To assign the value of \(j\) to \(k\) when \(i == 7\) is false, enclose the last operand in parentheses:

\[
\text{int} \ i,j,k; \\
(i == 7) \ ? \ j ++ : (k = j);
\]

Cast expressions

A cast operator is used for explicit type conversions. It converts the value of an expression to a specified type.

The following cast operators are supported:

- "Cast operator ()"  
- "The static_cast operator (C++ only)" on page 148  
- "The reinterpret_cast operator (C++ only)" on page 149  
- "The const_cast operator (C++ only)" on page 150  
- "The dynamic_cast operator (C++ only)" on page 151

Cast operator ()

Cast expression syntax

\[
\text{expression}
\]

The result of this operation is not an lvalue. The result of this operation is an lvalue if \(type\) is a reference; in all other cases, the result is an rvalue.
The following demonstrates the use of the cast operator to dynamically create an integer array of size 10:

```c
#include <stdlib.h>

int main(void) {
    int* myArray = (int*) malloc(10 * sizeof(int));
    free(myArray);
    return 0;
}
```

The malloc library function returns a void pointer that points to memory that will hold an object of the size of its argument. The statement `int* myArray = (int*) malloc(10 * sizeof(int))` does the following:

- Creates a void pointer that points to memory that can hold ten integers.
- Converts that void pointer into an integer pointer with the use of the cast operator.
- Assigns that integer pointer to `myArray`. Because a name of an array is the same as a pointer to the initial element of the array, `myArray` is an array of ten integers stored in the memory created by the call to malloc().

C++

In C++ you can also use the following in cast expressions:

- Function-style casts
- C++ conversion operators, such as `static_cast`.

Function-style notation converts the value of `expression` to the type `type`:

```
expression(type)
```

The following example shows the same value cast with a C-style cast, the C++ function-style cast, and a C++ cast operator:

```cpp
#include <iostream>
using namespace std;

int main() {
    float num = 98.76;
    int x1 = (int) num;
    int x2 = int(num);
    int x3 = static_cast<int>(num);
    
    cout << "x1= " << x1 << endl;
    cout << "x2= " << x2 << endl;
    cout << "x3= " << x3 << endl;
}
```

The following is the output of the above example:

```
x1 = 98
x2 = 98
x3 = 98
```

The integer `x1` is assigned a value in which `num` has been explicitly converted to an `int` with the C-style cast. The integer `x2` is assigned a value that has been converted with the function-style cast. The integer `x3` is assigned a value that has been converted with the `static_cast` operator.

A cast is a valid lvalue if its operand is an lvalue. In the following simple assignment expression, the right-hand side is first converted to the specified type, then to the type of the inner left-hand side expression, and the result is stored. The value is converted back to the specified type, and becomes the value of the assignment. In the following example, `i` is of type `char *`.

```c
(int)i = 8    // This is equivalent to the following expression
(int)(i = (char*) (int)(8))
```
For compound assignment operation applied to a cast, the arithmetic operator of the compound assignment is performed using the type resulting from the cast, and then proceeds as in the case of simple assignment. The following expressions are equivalent. Again, i is of type char *.

\[(\text{int})i += 8 \quad // \text{This is equivalent to the following expression}\]
\[(\text{int})(i = (\text{char}*)(\text{int})(\text{int})i = 8))\]

For C++, the operand of a cast expression can have class type. If the operand has class type, it can be cast to any type for which the class has a user-defined conversion function. Casts can invoke a constructor, if the target type is a class, or they can invoke a conversion function, if the source type is a class. They can be ambiguous if both conditions hold.

**Related reference**

### The static_cast operator (C++ only)

The **static_cast operator** converts a given expression to a specified type.

**static_cast operator syntax**

\[
\text{static_cast \\ \\
\quad \quad \text{Type} \quad \text{---} \quad \text{---} \quad \text{---} \quad \text{expression}
\]

The following is an example of the static_cast operator.

```cpp
#include <iostream>
using namespace std;

int main() {
    int j = 41;
    int v = 4;
    float m = j/v;
    float d = static_cast<float>(j)/v;
    cout << "m = " << m << endl;
    cout << "d = " << d << endl;
}
```

The following is the output of the above example:

m = 10.25

In this example, \(m = j/v\); produces an answer of type int because both \(j\) and \(v\) are integers. Conversely, \(d = \text{static_cast<float>(j)/v}\); produces an answer of type float. The static_cast operator converts variable \(j\) to a type float. This allows the compiler to generate a division with an answer of type float. All static_cast operators resolve at compile time and do not remove any const or volatile modifiers.

Applying the static_cast operator to a null pointer will convert it to a null pointer value of the target type.

You can explicitly convert a pointer of a type A to a pointer of a type B if A is a base class of B. If A is not a base class of B, a compile-time error will result.

You may cast an lvalue of a type A to a type B& if the following are true:
- A is a base class of B
- You are able to convert a pointer of type A to a pointer of type B
• The type B has the same or greater const or volatile qualifiers than type A
• A is not a virtual base class of B

The result is an lvalue of type B.

A pointer to member type can be explicitly converted into a different pointer to member type if both types are pointers to members of the same class. This form of explicit conversion may also take place if the pointer to member types are from separate classes, however one of the class types must be derived from the other.

Related reference
"User-defined conversions" on page 316
"Type-based aliasing" on page 88

The reinterpret_cast operator (C++ only)

A reinterpret_cast operator handles conversions between unrelated types.

reinterpret_cast operator syntax

```
<expression>::<Type>()
```

The reinterpret_cast operator produces a value of a new type that has the same bit pattern as its argument. You cannot cast away a const or volatile qualification. You can explicitly perform the following conversions:

• A pointer to any integral type large enough to hold it
• A value of integral or enumeration type to a pointer
• A pointer to a function to a pointer to a function of a different type
• A pointer to an object to a pointer to an object of a different type
• A pointer to a member to a pointer to a member of a different class or type, if the types of the members are both function types or object types

A null pointer value is converted to the null pointer value of the destination type.

Given an lvalue expression of type T and an object x, the following two conversions are synonymous:

• reinterpret_cast<T&>(x)
• *reinterpret_cast<T*>(&x)

C++ also supports C-style casts. The two styles of explicit casts have different syntax but the same semantics, and either way of reinterpretating one type of pointer as an incompatible type of pointer is usually invalid. The reinterpret_cast operator, as well as the other named cast operators, is more easily spotted than C-style casts, and highlights the paradox of a strongly typed language that allows explicit casts.

The C++ compiler detects and quietly fixes most but not all violations. It is important to remember that even though a program compiles, its source code may not be completely correct. On some platforms, performance optimizations are predicated on strict adherence to standard aliasing rules. Although the C++ compiler tries to help with type-based aliasing violations, it cannot detect all possible cases.

The following example violates the aliasing rule, but will execute as expected when compiled unoptimized in C++ or in K&R C or with NOANSIALIAS. It will also successfully compile optimized in C++ with ANSIALIAS, but will not necessarily execute as expected. The offending line 7 causes an old or uninitialized value for x to be printed.

```c
1 extern int y = 7;
2
3 int main() {
```
The next code example contains an incorrect cast that the compiler cannot even detect because the cast is across two different files.

```c
/* separately compiled file 1 */
extern float f;
extern int * int_pointer_to_f = (int *) &f; /* suspicious cast */

/* separately compiled file 2 */
extern float f;
extern int * int_pointer_to_f;
f = 1.0;
int i = *int_pointer_to_f; /* no suspicious cast but wrong */
```

In line 8, there is no way for the compiler to know that \( f = 1.0 \) is storing into the same object that \( i = *\text{int_pointer_to_f} \) is loading from.

Related reference

"User-defined conversions" on page 316

The const_cast operator (C++ only)

A \textit{const_cast} operator is used to add or remove a \texttt{const} or \texttt{volatile} modifier to or from a type.

\textbf{const_cast operator syntax}

\begin{verbatim}
const_cast <Type>(expression)
\end{verbatim}

\textit{Type} and the type of \textit{expression} may only differ with respect to their \texttt{const} and \texttt{volatile} qualifiers. Their cast is resolved at compile time. A single \textit{const_cast} expression may add or remove any number of \texttt{const} or \texttt{volatile} modifiers.

The result of a \textit{const_cast} expression is an rvalue unless \textit{Type} is a reference type. In this case, the result is an lvalue.

Types can not be defined within \textit{const_cast}.

The following demonstrates the use of the \textit{const_cast} operator:

```c
#include <iostream>
using namespace std;

void f(int* p) {
    cout << *p << endl;
}

int main(void) {
    const int a = 10;
    const int* b = &a;

    // Function f() expects int*, not const int*
    // f(b);
    int* c = const_cast<int*>(b);
    f(c);

    // Lvalue is const
    // *b = 20;
}```
// Undefined behavior
// *c = 30;

int a1 = 40;
const int* b1 = &a1;
int* c1 = const_cast<int*>(b1);

// Integer a1, the object referred to by c1, has not been declared const
*c1 = 50;

return 0;
}

The compiler will not allow the function call f(b). Function f() expects a pointer to an int, not a const int. The statement int* c = const_cast<int*>(b) returns a pointer c that refers to a without the const qualification of a. This process of using const_cast to remove the const qualification of an object is called casting away constness. Consequently the compiler will allow the function call f(c).

The compiler would not allow the assignment *b = 20 because b points to an object of type const int. The compiler will allow the *c = 30, but the behavior of this statement is undefined. If you cast away the constness of an object that has been explicitly declared as const, and attempt to modify it, the results are undefined.

However, if you cast away the constness of an object that has not been explicitly declared as const, you can modify it safely. In the above example, the object referred to by b1 has not been declared const, but you cannot modify this object through b1. You may cast away the constness of b1 and modify the value to which it refers.

The dynamic_cast operator (C++ only)

The dynamic_cast operator performs type conversions at run time. The dynamic_cast operator guarantees the conversion of a pointer to a base class to a pointer to a derived class, or the conversion of an lvalue referring to a base class to a reference to a derived class. A program can thereby use a class hierarchy safely. This operator and the typeid operator provide runtime type information (RTTI) support in C++.

The expression dynamic_cast<T>(v) converts the expression v to type T. Type T must be a pointer or reference to a complete class type or a pointer to void. If T is a pointer and the dynamic_cast operator fails, the operator returns a null pointer of type T. If T is a reference and the dynamic_cast operator fails, the operator throws the exception std::bad_cast. You can find this class in the standard library header <typeinfo>.

If T is a void pointer, then dynamic_cast will return the starting address of the object pointed to by v. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {
    virtual ~A() { }
};

struct B : A { }

int main() {
    B bobj;
```
```cpp
A* ap = &bobj;
void * vp = dynamic_cast<void *>(ap);
cout << "Address of vp : " << vp << endl;
cout << "Address of bobj: " << &bobj << endl;
}
```

The output of this example will be similar to the following. Both vp and &bobj will refer to the same address:

Address of vp : 12FF6C
Address of bobj: 12FF6C

The primary purpose for the `dynamic_cast` operator is to perform type-safe downcasts. A downcast is the conversion of a pointer or reference to a class A to pointer or reference to a class B, where class A is a base class of B. The problem with downcasts is that a pointer of type `A*` can and must point to any object of a class that has been derived from A. The `dynamic_cast` operator ensures that if you convert a pointer of class A to a pointer of a class B, the object that A points to belongs to class B or a class derived from B.

The following example demonstrates the use of the `dynamic_cast` operator:

```cpp
#include <iostream>
using namespace std;

struct A {
    virtual void f() { cout << "Class A" << endl; }
};

struct B : A {
    virtual void f() { cout << "Class B" << endl; }
};

struct C : A {
    virtual void f() { cout << "Class C" << endl; }
};

void f(A* arg) {
    B* bp = dynamic_cast<B*>(arg);
    C* cp = dynamic_cast<C*>(arg);
    if (bp)
        bp->f();
    else if (cp)
        cp->f();
    else
        arg->f();
};

int main() {
    A aobj;
    C cobj;
    A* ap = &cobj;
    A* ap2 = &aobj;
    f(ap);
    f(ap2);
}
```

The following is the output of the above example:

Class C
Class A

The function f() determines whether the pointer arg points to an object of type A, B, or C. The function does this by trying to convert arg to a pointer of type B, then to a pointer of type C, with the `dynamic_cast` operator. If the `dynamic_cast` operator succeeds, it returns a pointer that points to the object denoted by arg. If `dynamic_cast` fails, it returns 0.
You may perform downcasts with the `dynamic_cast` operator only on polymorphic classes. In the above example, all the classes are polymorphic because class `A` has a virtual function. The `dynamic_cast` operator uses the runtime type information generated from polymorphic classes.

## Compound literal expressions

A **compound literal** is a postfix expression that provides an unnamed object whose value is given by an initializer list. The C99 language feature allows you to pass parameters to functions without the need for temporary variables. It is useful for specifying constants of an aggregate type (arrays, structures, and unions) when only one instance of such types is needed.

The syntax for a compound literal resembles that of a cast expression. However, a compound literal is an lvalue, while the result of a cast expression is not. Furthermore, a cast can only convert to scalar types or `void`, whereas a compound literal results in an object of the specified type.

### Compound literal syntax

```c
(type_name) {initializer_list}
```

The `type_name` can be any data type, and user-defined types. It can be an array of unknown size, but not a variable length array. If the type is an array of unknown size, the size is determined by the initializer list.

The following example passes a constant structure variable of type `point` containing two integer members to the function `drawline`:

```c
drawline((struct point){6,7});
```

If the compound literal occurs outside the body of a function, the initializer list must consist of constant expressions, and the unnamed object has static storage duration. If the compound literal occurs within the body of a function, the initializer list need not consist of constant expressions, and the unnamed object has automatic storage duration.

## new expressions (C++ only)

The `new` operator provides dynamic storage allocation.

### new operator syntax

```c
::new (argument_list) new_type(initial_value)
```

If you prefix `new` with the scope resolution operator (::), the global `operator new()` is used. If you specify an `argument_list`, the overloaded `new` operator that corresponds to that `argument_list` is used. The `type` is an existing built-in or user-defined type. A `new_type` is a type that has not already been defined and can include type specifiers and declarators.
An allocation expression containing the `new` operator is used to find storage in free store for the object being created. The `new expression` returns a pointer to the object created and can be used to initialize the object. If the object is an array, a pointer to the initial element is returned.

You cannot use the `new` operator to allocate function types, `void`, or incomplete class types because these are not object types. However, you can allocate pointers to functions with the `new` operator. You cannot create a reference with the `new` operator.

When the object being created is an array, only the first dimension can be a general expression. All subsequent dimensions must be constant integral expressions. The first dimension can be a general expression even when an existing type is used. You can create an array with zero bounds with the `new` operator. For example:

```c
char * c = new char[0];
```

In this case, a pointer to a unique object is returned.

An object created with `operator new()` or `operator new[]()` exists until the `operator delete()` or `operator delete[]()` is called to deallocate the object's memory. A delete operator or a destructor will not be implicitly called for an object created with a `new` that has not been explicitly deallocated before the end of the program.

If parentheses are used within a new type, parentheses should also surround the new type to prevent syntax errors.

In the following example, storage is allocated for an array of pointers to functions:

```c
void f();
void g();

int main(void)
{
    void (**)p(), (**q);
    // declare p and q as pointers to pointers to void functions
    p = new (void (*[3])());
    // p now points to an array of pointers to functions
    q = new void(*[3])(); // error
    // error - bound as 'q = (new void) (*[3])();'
    p[0] = f; // p[0] to point to function f
    q[2] = g; // q[2] to point to function g
    p[0](); // call f()
    q[2](); // call g()
    return (0);
}
```

However, the second use of `new` causes an erroneous binding of `q = (new void) (*[3])()`.

The type of the object being created cannot contain class declarations, enumeration declarations, or `const` or `volatile` types. It can contain pointers to `const` or `volatile` objects.

For example, `const char*` is allowed, but `char* const` is not.

### Placement syntax

Additional arguments can be supplied to `new` by using the `argument_list`, also called the placement syntax. If placement arguments are used, a declaration of `operator new()` or `operator new[]()` with these arguments must exist. For example:

```c
#include <new>
using namespace std;
```
class X
{
public:
    void* operator new(size_t, int, int){ /* ... */ }
};

// ...
int main ()
{
    X* ptr = new(1,2) X;
}

The placement syntax is commonly used to invoke the global placement new function. The global placement new function initializes an object or objects at the location specified by the placement argument in the placement new expression. This location must address storage that has previously been allocated by some other means, because the global placement new function does not itself allocate memory. In the following example, no new memory is allocated by the calls new(whole) X(8);, new(seg2) X(9);, or new(seg3) X(10);. Instead, the constructors X(8), X(9), and X(10) are called to reinitialize the memory allocated to the buffer whole.

Because placement new does not allocate memory, you should not use delete to deallocate objects created with the placement syntax. You can only delete the entire memory pool (delete whole). In the example, you can keep the memory buffer but destroy the object stored in it by explicitly calling a destructor.

#include <new>
class X
{
public:
    X(int n): id(n){ }
    ~X(){ }
private:
    int id;
    // ...
};

int main()
{
    char* whole = new char[ 3 * sizeof(X) ]; // a 3-part buffer
    X* p1 = new(whole) X(8); // fill the front
    char* seg2 = &whole[ sizeof(X) ]; // mark second segment
    X* p2 = new(seg2) X(9); // fill second segment
    char* seg3 = &whole[ 2 * sizeof(X) ]; // mark third segment
    X* p3 = new(seg3) X(10); // fill third segment
    p2->~X(); // clear only middle segment, but keep the buffer
    // ...
    return 0;
}

The placement new syntax can also be used for passing parameters to an allocation routine rather than to a constructor.
Initialization of objects created with the new operator

You can initialize objects created with the `new` operator in several ways. For nonclass objects, or for class objects without constructors, a `new initializer` expression can be provided in a new expression by specifying `(expression)` or `()`. For example:

```cpp
double* pi = new double(3.1415926);
int* score = new int(89);
float* unknown = new float();
```

If a class does not have a default constructor, the new initializer must be provided when any object of that class is allocated. The arguments of the new initializer must match the arguments of a constructor.

You cannot specify an initializer for arrays. You can initialize an array of class objects only if the class has a default constructor. The constructor is called to initialize each array element (class object).

Initialization using the new initializer is performed only if `new` successfully allocates storage.

Handling new allocation failure

When the `new` operator creates a new object, it calls the operator `new()` or `operator new[]()` function to obtain the needed storage.

When `new` cannot allocate storage to create a new object, it calls a `new handler` function if one has been installed by a call to `set_new_handler()`. The `std::set_new_handler()` function is declared in the header `<new>`. Use it to call a new handler you have defined or the default new handler.

Your new handler must perform one of the following:

- obtain more storage for memory allocation, then return
- throw an exception of type `std::bad_alloc` or a class derived from `std::bad_alloc`
- call either `abort()` or `exit()`

The `set_new_handler()` function has the prototype:

```cpp
typedef void(*PNH)();
PNH set_new_handler(PNH);
```

`set_new_handler()` takes as an argument a pointer to a function (the new handler), which has no arguments and returns void. It returns a pointer to the previous new handler function.

If you do not specify your own `set_new_handler()` function, `new` throws an exception of type `std::bad_alloc`.

The following program fragment shows how you could use `set_new_handler()` to return a message if the `new` operator cannot allocate storage:

```cpp
#include <iostream>
#include <new>
#include <cstdlib>
using namespace std;
```
void no_storage()
{
    std::cerr << "Operator new failed: no storage is available.\n";
    std::exit(1);
}

int main(void)
{
    std::set_new_handler(&no_storage);
    // Rest of program ...}

If the program fails because new cannot allocate storage, the program exits with the message:
Operator new failed: no storage is available.

---

**delete expressions (C++ only)**

The `delete` operator destroys the object created with `new` by deallocating the memory associated with the object.

The `delete` operator has a `void` return type.

```
delete operator syntax

```

The operand of `delete` must be a pointer returned by `new`, and cannot be a pointer to constant. Deleting a null pointer has no effect.

The `delete[]` operator frees storage allocated for array objects created with `new[]`. The `delete` operator frees storage allocated for individual objects created with `new`.

```
delete[] operator syntax

```

The result of deleting an array object with `delete` is undefined, as is deleting an individual object with `delete[]`. The array dimensions do not need to be specified with `delete[]`.

The result of any attempt to access a deleted object or array is undefined.

If a destructor has been defined for a class, `delete` invokes that destructor. Whether a destructor exists or not, `delete` frees the storage pointed to by calling the function `operator delete()` of the class if one exists.

The global `::operator delete()` is used if:
- The class has no operator `delete()`.
- The object is of a nonclass type.
- The object is deleted with the `::delete` expression.

The global `::operator delete[]()` is used if:
- The class has no operator `delete[]()`.
• The object is of a nonclass type
• The object is deleted with the ::delete[] expression.

The default global operator delete() only frees storage allocated by the default global operator new(). The default global operator delete[]( ) only frees storage allocated for arrays by the default global operator new[]( ).

Operator precedence and associativity

Two operator characteristics determine how operands group with operators: precedence and associativity. Precedence is the priority for grouping different types of operators with their operands. Associativity is the left-to-right or right-to-left order for grouping operands to operators that have the same precedence. An operator's precedence is meaningful only if other operators with higher or lower precedence are present. Expressions with higher-precedence operators are evaluated first. The grouping of operands can be forced by using parentheses.

For example, in the following statements, the value of 5 is assigned to both a and b because of the right-to-left associativity of the = operator. The value of c is assigned to b first, and then the value of b is assigned to a.

```
b = 9;
c = 5;
a = b = c;
```

Because the order of subexpression evaluation is not specified, you can explicitly force the grouping of operands with operators by using parentheses.

In the expression
```
a + b * c / d
```

the * and / operations are performed before + because of precedence. b is multiplied by c before it is divided by d because of associativity.

The following tables list the C and C++ language operators in order of precedence and show the direction of associativity for each operator. Operators that have the same rank have the same precedence.

Examples of expressions and precedence

The parentheses in the following expressions explicitly show how the compiler groups operands and operators.
total = (4 + (5 * 3));
total = (((8 * 5) / 10) / 3);
total = (10 + (5/3));

If parentheses did not appear in these expressions, the operands and operators would be grouped in the
same manner as indicated by the parentheses. For example, the following expressions produce the same
output.

total = (4+(5*3));
total = 4+5*3;

Because the order of grouping operands with operators that are both associative and commutative is not
specified, the compiler can group the operands and operators in the expression:

total = price + prov_tax +
city_tax;

in the following ways (as indicated by parentheses):

total = (price + (prov_tax + city_tax));
total = ((price + prov_tax) + city_tax);
total = ((price + city_tax) + prov_tax);

The grouping of operands and operators does not affect the result unless one ordering causes an overflow
and another does not. For example, if price = 32767, prov_tax = -42, and city_tax = 32767, and all
three of these variables have been declared as integers, the third statement total = ((price + city_tax) +
prov_tax) will cause an integer overflow and the rest will not.

Because intermediate values are rounded, different groupings of floating-point operators may give different
results.

In certain expressions, the grouping of operands and operators can affect the result. For example, in the
following expression, each function call might be modifying the same global variables.

a = b() + c() + d();

This expression can give different results depending on the order in which the functions are called.

If the expression contains operators that are both associative and commutative and the order of grouping
operands with operators can affect the result of the expression, separate the expression into several
expressions. For example, the following expressions could replace the previous expression if the called
functions do not produce any side effects that affect the variable a.

a = b();
a += c();
a += d();

The order of evaluation for function call arguments or for the operands of binary operators is not specified.
Therefore, the following expressions are ambiguous:

z = (x * ++y) / func1(y);
func2(++i, x[i]);

If y has the value of 1 before the first statement, it is not known whether or not the value of 1 or 2 is
passed to func1(). In the second statement, if i has the value of 1 before the expression is evaluated, it is
not known whether x[1] or x[2] is passed as the second argument to func2().
Chapter 7. Statements

A statement, the smallest independent computational unit, specifies an action to be performed. In most cases, statements are executed in sequence. The following is a summary of the statements available in C and C++:

- Labeled statements
- Expression statements
- Block statements
- Selection statements
- Iteration statements
- Jump statements
- Declaration statements
- C++ try blocks
- Null statement

Labeled statements

There are three kinds of labels: identifier, case, and default.

Labeled statement syntax

```
| identifier | : | statement |
```

The label consists of the `identifier` and the colon (`:`) character.

- A label name must be unique within the function in which it appears.
- In C++, an identifier label may only be used as the target of a `goto` statement. A `goto` statement can use a label before its definition. Identifier labels have their own namespace; you do not have to worry about identifier labels conflicting with other identifiers. However, you may not redefine a label within a function.

Case and default label statements only appear in `switch` statements. These labels are accessible only within the closest enclosing `switch` statement.

Case statement syntax

```
| case | constant_expression | : | statement |
```

Default statement syntax

```
| default | : | statement |
```

The following are examples of labels:

```c
comment_complete : ;    /* null statement label */
test_for_null : if (NULL == pointer)
```
Labels as values (IBM extension)

The address of a label defined in the current function or a containing function can be obtained and used as a value wherever a constant of type `void*` is valid. The address is the return value when the label is the operand of the unary operator `&&`. The ability to use the address of label as a value is an extension to C99 and C++, implemented to facilitate porting programs developed with GNU C.

In the following example, the computed goto statements use the values of `label1` and `label2` to jump to those spots in the function.

```c
int main()
{
    void * ptr1, *ptr2;
    ...
    label1: ...
    ...
    label2: ...
    ...
    ptr1 = &&label1;
    ptr2 = &&label2;
    if (...) {
        goto *ptr1;
    } else {
        goto *ptr2;
    }
    ...
}
```

Expression statements

An expression statement contains an expression. The expression can be null.

### Expression statement syntax

```
expression;
```

An expression statement evaluates `expression`, then discards the value of the expression. An expression statement without an expression is a null statement.

The following are examples of statements:

```c
printf("Account Number: \n"); /* call to the printf */
marks = dollars * exch_rate; /* assignment to marks */
(difference < 0) ? ++losses : ++gain; /* conditional increment */
```

Resolution of ambiguous statements (C++ only)

The C++ syntax does not disambiguate between expression statements and declaration statements. The ambiguity arises when an expression statement has a function-style cast as its left-most subexpression. (Note that, because C does not support function-style casts, this ambiguity does not occur in C programs.) If the statement can be interpreted both as a declaration and as an expression, the statement is interpreted as a declaration statement.
Note: The ambiguity is resolved only on a syntactic level. The disambiguation does not use the meaning of the names, except to assess whether or not they are type names.

The following expressions disambiguate into expression statements because the ambiguous subexpression is followed by an assignment or an operator. type_spec in the expressions can be any type specifier:

type_spec(i)++; // expression statement
type_spec(i,3)<<d; // expression statement
type_spec(i)->l=24; // expression statement

In the following examples, the ambiguity cannot be resolved syntactically, and the statements are interpreted as declarations. type_spec is any type specifier:

type_spec(*i)(int); // declaration
type_spec(j)[5]; // declaration
type_spec(m) = { 1, 2 }; // declaration
type_spec(*k) (float(3)); // declaration

The last statement above causes a compile-time error because you cannot initialize a pointer with a float value.

Any ambiguous statement that is not resolved by the above rules is by default a declaration statement. All of the following are declaration statements:

type_spec(a); // declaration
type_spec(*b)(); // declaration
type_spec(c)=23; // declaration
type_spec(d),e,f,g=0; // declaration
type_spec(h)(e,3); // declaration

Block statements

A block statement, or compound statement, lets you group any number of data definitions, declarations, and statements into one statement. All definitions, declarations, and statements enclosed within a single set of braces are treated as a single statement. You can use a block wherever a single statement is allowed.

Block statement syntax

A block defines a local scope. If a data object is usable within a block and its identifier is not redefined, all nested blocks can use that data object.
Example of blocks

The following program shows how the values of data objects change in nested blocks:

```c
/**
 * This example shows how data objects change in nested blocks.
**/
#include <stdio.h>

int main(void)
{
    int x = 1; /* Initialize x to 1 */
    int y = 3;
    if (y > 0)
    {
        int x = 2; /* Initialize x to 2 */
        printf("second x = %4d\n", x);
    }
    printf("first x = %4d\n", x);
    return(0);
}
```

The program produces the following output:

```
second x = 2
first x = 1
```

Two variables named `x` are defined in `main`. The first definition of `x` retains storage while `main` is running. However, because the second definition of `x` occurs within a nested block, `printf("second x = %4d\n", x);` recognizes `x` as the variable defined on the previous line. Because `printf("first x = %4d\n", x);` is not part of the nested block, `x` is recognized as the first definition of `x`.

Selection statements

Selection statements consist of the following types of statements:

- The `if` statement
- The `switch` statement

The `if` statement

An `if` statement is a selection statement that allows more than one possible flow of control.

- **C++** An `if` statement lets you conditionally process a statement when the specified test expression, implicitly converted to `bool`, evaluates to `true`. If the implicit conversion to `bool` fails the program is ill-formed.

- **C** In C, an `if` statement lets you conditionally process a statement when the specified test expression evaluates to a nonzero value. The test expression must be of arithmetic or pointer type.

You can optionally specify an `else` clause on the `if` statement. If the test expression evaluates to `false` (or in C, a zero value) and an `else` clause exists, the statement associated with the `else` clause runs. If the test expression evaluates to `true`, the statement following the expression runs and the `else` clause is ignored.
if statement syntax

```
if (expression) statement [else statement]
```

When if statements are nested and else clauses are present, a given else is associated with the closest preceding if statement within the same block.

A single statement following any selection statements (if, switch) is treated as a compound statement containing the original statement. As a result any variables declared on that statement will be out of scope after the if statement. For example:

```
if (x)
  int i;
```

is equivalent to:

```
if (x)
  { int i; }
```

Variable i is visible only within the if statement. The same rule applies to the else part of the if statement.

Examples of if statements

The following example causes grade to receive the value A if the value of score is greater than or equal to 90.

```
if (score >= 90)
  grade = 'A';
```

The following example displays Number is positive if the value of number is greater than or equal to 0. If the value of number is less than 0, it displays Number is negative.

```
if (number >= 0)
  printf("Number is positive\n");
else
  printf("Number is negative\n");
```

The following example shows a nested if statement:

```
if (paygrade == 7)
  if (level >= 0 && level <= 8)
    salary *= 1.05;
  else
    salary *= 1.04;
else
  salary *= 1.06;
cout << "salary is " << salary << endl;
```

The following example shows a nested if statement that does not have an else clause. Because an else clause always associates with the closest if statement, braces might be needed to force a particular else clause to associate with the correct if statement. In this example, omitting the braces would cause the else clause to associate with the nested if statement.

```
if (kegs > 0) {
  if (furlongs > kegs)
    fxph = furlongs/kegs;
}
else
  fxph = 0;
```
The following example shows an if statement nested within an else clause. This example tests multiple conditions. The tests are made in order of their appearance. If one test evaluates to a nonzero value, a statement runs and the entire if statement ends.

```c
if (value > 0)
  ++increase;
else if (value == 0)
  ++break_even;
else
  ++decrease;
```

## The switch statement

A *switch statement* is a selection statement that lets you transfer control to different statements within the switch body depending on the value of the switch expression. The switch expression must evaluate to an integral or enumeration value. The body of the switch statement contains *case clauses* that consist of:

- A case label
- An optional default label
- A case expression
- A list of statements.

If the value of the switch expression equals the value of one of the case expressions, the statements following that case expression are processed. If not, the default label statements, if any, are processed.

### switch statement syntax

```
switch(expression) switch_body
```

The switch body is enclosed in braces and can contain definitions, declarations, case clauses, and a default clause. Each case clause and default clause can contain statements.

```
{ type_definition file_scope_data_declaration block_scope_data_declaration case_clause default_clause

case_clause } case_clause
```

**Note:** An initializer within a type_definition, file_scope_data_declaration or block_scope_data_declaration is ignored.

A case clause contains a case label followed by any number of statements. A case clause has the form:

### Case clause syntax

```
case_label statement
```
A case label contains the word case followed by an integral constant expression and a colon. The value of each integral constant expression must represent a different value; you cannot have duplicate case labels. Anywhere you can put one case label, you can put multiple case labels. A case label has the form:

**Case label syntax**

```
  case - integral_constant_expression - :
```

A default clause contains a default label followed by one or more statements. You can put a case label on either side of the default label. A switch statement can have only one default label. A default_clause has the form:

**Default clause statement**

```
  default - : 
```

The switch statement passes control to the statement following one of the labels or to the statement following the switch body. The value of the expression that precedes the switch body determines which statement receives control. This expression is called the switch expression.

The value of the switch expression is compared with the value of the expression in each case label. If a matching value is found, control is passed to the statement following the case label that contains the matching value. If there is no matching value but there is a default label in the switch body, control passes to the default labelled statement. If no matching value is found, and there is no default label anywhere in the switch body, no part of the switch body is processed.

When control passes to a statement in the switch body, control only leaves the switch body when a break statement is encountered or the last statement in the switch body is processed.

If necessary, an integral promotion is performed on the controlling expression, and all expressions in the case statements are converted to the same type as the controlling expression. The switch expression can also be of class type if there is a single conversion to integral or enumeration type.

**Restrictions on switch statements**

You can put data definitions at the beginning of the switch body, but the compiler does not initialize auto and register variables at the beginning of a switch body. You can have declarations in the body of the switch statement.

You cannot use a switch statement to jump over initializations.

- **C** When the scope of an identifier with a variably modified type includes a case or default label of a switch statement, the entire switch statement is considered to be within the scope of that identifier. That is, the declaration of the identifier must precede the switch statement.

- **C++** In C++, you cannot transfer control over a declaration containing an explicit or implicit initializer unless the declaration is located in an inner block that is completely bypassed by the transfer of control. All declarations within the body of a switch statement that contain initializers must be contained in an inner block.
**Examples of switch statements**

The following switch statement contains several case clauses and one default clause. Each clause contains a function call and a break statement. The break statements prevent control from passing down through each statement in the switch body.

If the switch expression evaluated to '/', the switch statement would call the function divide. Control would then pass to the statement following the switch body.

```c
char key;
printf("Enter an arithmetic operator\n");
scanf("%c", &key);
switch (key) {
    case '+':
        add();
        break;
    case '-':
        subtract();
        break;
    case '*':
        multiply();
        break;
    case '/':
        divide();
        break;
    default:
        printf("invalid key\n");
        break;
}
```

If the switch expression matches a case expression, the statements following the case expression are processed until a break statement is encountered or the end of the switch body is reached. In the following example, break statements are not present. If the value of text[i] is equal to 'A', all three counters are incremented. If the value of text[i] is equal to 'a', lettera and total are increased. Only total is increased if text[i] is not equal to 'A' or 'a'.

```c
char text[100];
int capa, lettera, total;
// ...
for (i=0; i<sizeof(text); i++) {
    switch (text[i]) {
        case 'A':
            capa++;
        case 'a':
            lettera++;
        default:
            total++;
    }
}
```

The following switch statement performs the same statements for more than one case label:
This example contains a switch statement that performs the same statement for more than one case label.

```c
#include <stdio.h>

int main(void)
{
    int month;

    /* Read in a month value */
    printf("Enter month: ");
    scanf("%d", &month);

    /* Tell what season it falls into */
    switch (month)
    {
    case 12:
    case 1:
    case 2:
        printf("month %d is a winter month\n", month);
        break;

    case 3:
    case 4:
    case 5:
        printf("month %d is a spring month\n", month);
        break;

    case 6:
    case 7:
    case 8:
        printf("month %d is a summer month\n", month);
        break;

    case 9:
    case 10:
    case 11:
        printf("month %d is a fall month\n", month);
        break;

    case 66:
    case 99:
    default:
        printf("month %d is not a valid month\n", month);
    }

    return(0);
}
```

If the expression `month` has the value 3, control passes to the statement:

```
printf("month %d is a spring month\n", month);
```

The `break` statement passes control to the statement following the `switch` body.
Iteration statements

Iteration statements consist of the following types of statements:

- The while statement
- The do statement
- The for statement

The while statement

A while statement repeatedly runs the body of a loop until the controlling expression evaluates to false (or 0 in C).

while statement syntax

```c
while (expression) statement
```

- C The expression must be of arithmetic or pointer type.
- C++ The expression must be convertible to bool.

The expression is evaluated to determine whether or not to process the body of the loop. If the expression evaluates to false, the body of the loop never runs. If the expression does not evaluate to false, the loop body is processed. After the body has run, control passes back to the expression. Further processing depends on the value of the condition.

A break, return, or goto statement can cause a while statement to end, even when the condition does not evaluate to false.

In the following example, item[index] triples and is printed out, as long as the value of the expression ++index is less than MAX_INDEX. When ++index evaluates to MAX_INDEX, the while statement ends.

```c
/*
 ** This example illustrates the while statement.
 **/

#define MAX_INDEX (sizeof(item) / sizeof(item[0]))
#include <stdio.h>

int main(void)
{
    static int item[] = { 12, 55, 62, 85, 102 };
    int index = 0;
    while (index < MAX_INDEX)
    {
```
The do statement

A do statement repeatedly runs a statement until the test expression evaluates to false (or 0 in C). Because of the order of processing, the statement is run at least once.

**do statement syntax**

```
do statement while (expression);
```

**C** The expression must be of arithmetic or pointer type. **C++** The controlling expression must be convertible to type bool.

The body of the loop is run before the controlling while clause is evaluated. Further processing of the do statement depends on the value of the while clause. If the while clause does not evaluate to false, the statement runs again. When the while clause evaluates to false, the statement ends.

A break, return, or goto statement can cause the processing of a do statement to end, even when the while clause does not evaluate to false.

**C++** A throw expression also can cause a while statement to end prior to the condition being evaluated.

The following example keeps incrementing i while i is less than 5:

```c
#include <stdio.h>

int main(void) {
    int i = 0;
    do {
        printf("Value of i: %d\n", i);
        ++i;
    } while (i < 5);
    return 0;
}
```

The following is the output of the above example:

```
Value of i: 1
Value of i: 2
Value of i: 3
Value of i: 4
Value of i: 5
```

The for statement

A for statement lets you do the following:
- Evaluate an expression before the first iteration of the statement (initialization)
- Specify an expression to determine whether or not the statement should be processed (the condition)
- Evaluate an expression after each iteration of the statement (often used to increment for each iteration)
- Repeatedly process the statement if the controlling part does not evaluate to false (or 0 in C).
for statement syntax

expression1 is the initialization expression. It is evaluated only before the statement is processed for the first time. You can use this expression to initialize a variable. You can also use this expression to declare a variable, provided that the variable is not declared as static (it must be automatic and may also be declared as register). If you declare a variable in this expression, or anywhere else in statement, that variable goes out of scope at the end of the for loop. If you do not want to evaluate an expression prior to the first iteration of the statement, you can omit this expression.

expression2 is the conditional expression. It is evaluated before each iteration of the statement. expression2 must be of arithmetic or pointer type. expression3 must be convertible to type bool.

If it evaluates to false (or 0 in C), the statement is not processed and control moves to the next statement following the for statement. If expression2 does not evaluate to false, the statement is processed. If you omit expression2, it is as if the expression had been replaced by true, and the for statement is not terminated by failure of this condition.

expression3 is evaluated after each iteration of the statement. This expression is often used for incrementing, decrementing, or assigning to a variable. This expression is optional.

A break, return, or goto statement can cause a for statement to end, even when the second expression does not evaluate to false. If you omit expression2, you must use a break, return, or goto statement to end the for statement.

Examples of for statements

The following for statement prints the value of count 20 times. The for statement initially sets the value of count to 1. After each iteration of the statement, count is incremented.

```c
int count;
for (count = 1; count <= 20; count++)
    printf("count = %d\n", count);
```

The following sequence of statements accomplishes the same task. Note the use of the while statement instead of the for statement.

```c
int count = 1;
while (count <= 20) {
    printf("count = %d\n", count);
    count++;
}
```

The following for statement does not contain an initialization expression:

```c
for (; index > 10; --index) {
    list[index] = var1 + var2;
    printf("list[%d] = %d\n", index, list[index]);
}
```

The following for statement will continue running until scanf receives the letter e:

```c
for (;;)
{
    scanf("%c", &letter);
    if (letter == '\n')
```
continue;
if (letter == 'e')
break;
printf("You entered the letter %c\n", letter);
}

The following for statement contains multiple initializations and increments. The comma operator makes this construction possible. The first comma in the for expression is a punctuator for a declaration. It declares and initializes two integers, i and j. The second comma, a comma operator, allows both i and j to be incremented at each step through the loop.

for (int i = 0, j = 50; i < 10; ++i, j += 50)
{
    cout << "i= " << i << " and j= " << j << endl;
}

The following example shows a nested for statement. It prints the values of an array having the dimensions [5][3].

for (row = 0; row < 5; row++)
    for (column = 0; column < 3; column++)
        printf("%d\n", table[row][column]);

The outer statement is processed as long as the value of row is less than 5. Each time the outer for statement is executed, the inner for statement sets the initial value of column to zero and the statement of the inner for statement is executed 3 times. The inner statement is executed as long as the value of column is less than 3.

Jump statements

Jump statements consist of the following types of statements:

- The break statement
- The continue statement
- The return statement
- The goto statement

The break statement

A break statement lets you end an iterative (do, for, or while) statement or a switch statement and exit from it at any point other than the logical end. A break may only appear on one of these statements.

**break statement syntax**

```
break;
```

In an iterative statement, the break statement ends the loop and moves control to the next statement outside the loop. Within nested statements, the break statement ends only the smallest enclosing do, for, switch, or while statement.

In a switch statement, the break passes control out of the switch body to the next statement outside the switch statement.
The continue statement

A continue statement ends the current iteration of a loop. Program control is passed from the continue statement to the end of the loop body.

A continue statement has the form:

```c
continue;
```

A continue statement can only appear within the body of an iterative statement, such as do, for, or while.

The continue statement ends the processing of the action part of an iterative statement and moves control to the loop continuation portion of the statement. For example, if the iterative statement is a for statement, control moves to the third expression in the condition part of the statement, then to the second expression (the test) in the condition part of the statement.

Within nested statements, the continue statement ends only the current iteration of the do, for, or while statement immediately enclosing it.

Examples of continue statements

The following example shows a continue statement in a for statement. The continue statement causes processing to skip over those elements of the array rates that have values less than or equal to 1.

```c
CCNRAA3
/**
 ** This example shows a continue statement in a for statement.
 **/
#include <stdio.h>
#define SIZE 5
int main(void)
{
    int i;
    static float rates[SIZE] = { 1.45, 0.05, 1.88, 2.00, 0.75 };

    printf("Rates over 1.00\n");
    for (i = 0; i < SIZE; i++)
    {
        if (rates[i] <= 1.00) /* skip rates <= 1.00 */
            continue;
        printf("rate = %.2f\n", rates[i]);
    }

    return(0);
}
```

The program produces the following output:

Rates over 1.00
rate = 1.45
rate = 1.88
rate = 2.00

The following example shows a continue statement in a nested loop. When the inner loop encounters a number in the array strings, that iteration of the loop ends. Processing continues with the third expression of the inner loop. The inner loop ends when the \'\0\' escape sequence is encountered.

```c
CCNRAA4
```
This program counts the characters in strings that are part of an array of pointers to characters. The count excludes the digits 0 through 9.

```c
#include <stdio.h>
#define SIZE 3

int main(void)
{
    static char *strings[SIZE] = { "ab", "c5d", "e5" };
    int i;
    int letter_count = 0;
    char *pointer;
    for (i = 0; i < SIZE; i++) /* for each string */
        for (pointer = strings[i]; *pointer != '\0'; ++pointer)
            /* if a number */
                if (*pointer >= '0' && *pointer <= '9')
                continue;
        letter_count++;
    printf("letter count = %d\n", letter_count);
    return(0);
}
```

The program produces the following output:
letter count = 5

The return statement

A return statement ends the processing of the current function and returns control to the caller of the function.

```
return statement syntax

```

A value-returning function should include a return statement, containing an expression.

- C If an expression is not given on a return statement in a function declared with a non-void return type, the compiler issues a warning message.

- C++ If an expression is not given on a return statement in a function declared with a non-void return type, the compiler issues an error message.

If the data type of the expression is different from the function return type, conversion of the return value takes place as if the value of the expression were assigned to an object with the same function return type.

For a function of return type void, a return statement is not strictly necessary. If the end of such a function is reached without encountering a return statement, control is passed to the caller as if a return statement without an expression were encountered. In other words, an implicit return takes place upon completion of the final statement, and control automatically returns to the calling function.
If a return statement is used, it must not contain an expression.

Examples of return statements

The following are examples of return statements:

```c
return;  /* Returns no value */
return result;  /* Returns the value of result */
return 1;  /* Returns the value 1 */
return (x * x);  /* Returns the value of x * x */
```

The following function searches through an array of integers to determine if a match exists for the variable number. If a match exists, the function match returns the value of i. If a match does not exist, the function match returns the value -1 (negative one).

```c
int match(int number, int array[], int n)
{
    int i;
    for (i = 0; i < n; i++)
        if (number == array[i])
            return (i);
    return(-1);
}
```

A function can contain multiple return statements. For example:

```c
void copy( int *a, int *b, int c)
{
    /* Copy array a into b, assuming both arrays are the same size */
    if (!a || !b)  /* if either pointer is 0, return */
        return;
    if (a == b)  /* if both parameters refer */
        return;  /* to same array, return */
    if (c == 0)  /* nothing to copy */
        return;
    for (int i = 0; i < c; ++i)  /* do the copying */
        b[i] = a[i];  /* implicit return */
}
```

In this example, the return statement is used to cause a premature termination of the function, similar to a break statement.

An expression appearing in a return statement is converted to the return type of the function in which the statement appears. If no implicit conversion is possible, the return statement is invalid.

The goto statement

A goto statement causes your program to unconditionally transfer control to the statement associated with the label specified on the goto statement.

goto statement syntax
Because the `goto` statement can interfere with the normal sequence of processing, it makes a program more difficult to read and maintain. Often, a `break` statement, a `continue` statement, or a function call can eliminate the need for a `goto` statement.

If an active block is exited using a `goto` statement, any local variables are destroyed when control is transferred from that block.

You cannot use a `goto` statement to jump over initializations.

A `goto` statement is allowed to jump within the scope of a variable length array, but not past any declarations of objects with variably modified types.

The following example shows a `goto` statement that is used to jump out of a nested loop. This function could be written without using a `goto` statement.

```
/**
 * This example shows a goto statement that is used to
 * jump out of a nested loop.
 */

#include <stdio.h>
void display(int matrix[3][3]);

int main(void)
{
    int matrix[3][3] = {1,2,3,4,5,2,8,9,10};
    display(matrix);
    return(0);
}

void display(int matrix[3][3])
{
    int i, j;
    for (i = 0; i < 3; i++)
        for (j = 0; j < 3; j++)
        {
            if ( (matrix[i][j] < 1) || (matrix[i][j] > 6) )
                goto out_of_bounds;
            printf("matrix[%d][%d] = %d\n", i, j, matrix[i][j]);
        }
    return;
    out_of_bounds: printf("number must be 1 through 6\n");
}
```

**Computed goto statement (IBM extension)**

A computed goto is a `goto` statement for which the target is a label from the same function. The address of the label is a constant of type `void*`, and is obtained by applying the unary label value operator `&&` to the label. The target of a computed goto is known at run time, and all computed goto statements from the same function will have the same targets. The language feature is an extension to C99 and C++, implemented to facilitate porting programs developed with GNU C.

**Computed goto statement syntax**
The `*expression` is an expression of type `void*`.

**Related reference**

“Labeled statements” on page 163

---

**Null statement**

The **null statement** performs no operation. It has the form:

```
goto *expression*;
```

A null statement can hold the label of a labeled statement or complete the syntax of an iterative statement.

The following example initializes the elements of the array `price`. Because the initializations occur within the `for` expressions, a statement is only needed to finish the `for` syntax; no operations are required.

```c
for (i = 0; i < 3; price[i++] = 0) ;
```

A null statement can be used when a label is needed before the end of a block statement. For example:

```c
void func(void) {
  if (error_detected)
    goto depart;
  /* further processing */
  depart: ; /* null statement required */
}
```

---

**Inline assembly statements (IBM extension)**

When the GENASM compiler option is in effect, the compiler provides support for embedded assembly code fragments among C source statements. This extension allows C programs to invoke IBM MVS™ system services directly via system-provided assembly macros.

The keyword `asm` stands for assembly code. When NOGENASM is in effect, the compiler recognizes and ignores the keyword `asm` in a declaration.

The syntax is as follows:

```
asm statement syntax — statement in local scope
```

```
asm <constraint>(<C_expression>) <output> <input> <clobbers>
```

input:

```
modifier <constraint>(<C_expression>)
```

---
**asm statement syntax — statement in global scope**

```
asm(code_format_string)
```

**volatile**
The qualifier `volatile` instructs the compiler to perform only minimal optimizations on the assembly block. The compiler cannot move any instructions across the implicit fences surrounding the assembly block. See [Example 1](#) for detailed usage information.

**code_format_string**
The `code_format_string` is the source text of the `asm` instructions and is a string literal similar to a `printf` format specifier.

**output**
The `output` consists of zero, one or more output operands, separated by commas. Each operand consists of a `constraint(C_expression)` pair. The output operand must be constrained by the `-` or `+` modifier (described below).

**input**
The `input` consists of zero, one or more input operands, separated by commas. Each operand consists of a `constraint(C_expression)` pair.

**clobbers**
`clobbers` is a comma-separated list of register names enclosed in double quotes. If an `asm` instruction updates registers that are not listed in the `input` or `output` of the `asm` statement, the registers must be listed as clobbered registers. The following register names are valid:

- `r0` or `R0` to `r15` or `R15`
  General purpose registers

**modifier**
The `modifier` can be one of the following operators:

- `_` Indicates that the operand is write-only for this instruction. The previous value is discarded and replaced by output data.
- `_+` Indicates that the operand is both read and written by the instruction.
- `&_` Indicates that the operand may be modified before the instruction is finished using the input operands; a register that is used as input should not be reused here.

  **Note:** The `_&` modifier is ignored in z/OS V1R9.

**constraint**
The `constraint` is a string literal that describes the kind of operand that is permitted, one character per constraint. The following constraints are supported:

- `a` Use an address register (general purpose register except `r0`)
- `d` Use a data register (equivalent to the `r` constraint)
- `g` Use a general register, memory, or immediate operand.
- `i` Use an immediate integer or string literal operand.
- `m` Use a memory operand supported by the machine.
n  Use an immediate integer.
o  Use a memory operand that is offsetable.
r  Use a general register.
s  Use a string literal operand.

0, 1, 2, ...
A matching constraint. Allocate the same register in output as in the corresponding input.

I, J, K
Constant values. Fold the expression in the operand and substitute the value into the \% specifier.
  - I — signed 16-bit
  - J — unsigned 16-bit shifted left 16 bits
  - K — unsigned 16-bit constant

XL  Use only the parameter constraints listed in this constraint. XL is an optional prefix, followed by a colon (:), to introduce any of the following parameter constraints:

DS  Do not generate a definition for the operand defined in the assembly statement; instead, substitute an assembly instruction to define the operand. Optionally, to specify the data size of the operand defined in the assembly statement, use a colon (:) followed by a positive integer. If you do not specify a data size, the size specified in the ASMDATASIZE option is used.

RP  The operand requires a register pair. Optionally, to specify the constraint for the register pair, specify a :, followed by the register_type, optionally followed by another : and an optional register_pair_flag. The register_pair_flag can be one of the following:
  - o  The operand needs an odd/even register pair.
  - e  The operand needs an even/odd register pair.

If you do not specify a register type, r (general purpose register) is used as the default. If you do not specify a register pair flag, e (even/odd pair) is used as the default.

NR  Use the named general purpose register. Use a colon (: ) followed by the general purpose register name (see below for acceptable register names).

Note: The XL constraints can be used for both input and output operands, with the exception of DS, which can only be used for output operands.

C_expression
The C_expression is a C expression whose value is used as the operand for the asm instruction. Output operands must be modifiable lvalues. The C_expression must be consistent with the constraint specified on it. For example, if i is specified, the operand must be an integer constant number.

Note: If pointer expressions are used in input or output, the assembly instructions should honor the ANSI aliasing rule (see "Type-based aliasing" on page 88 for more information). This means that indirect addressing using values in pointer expression operands should be consistent with the pointer types; otherwise, you must disable the ANSIALIAS option during compilation.

For more information on GENASM and ANSIALIAS options, see GENASM and ANSIALIAS options in the z/OS XL C/C++ User’s Guide.
Restrictions on inline assembly statements

The following restrictions are on the use of inline assembly statements:

- The assembler instructions must be self-contained within an `asm` statement. The `asm` statement can only be used to generate instructions. All connections to the rest of the program must be established through the output and input operand list.
- If an `asm` statement is used to define data, it cannot contain assembly instructions for other purposes.
- Only `asm` statements that are used to define data can exist in global scope.
- Each assembly statement can define only one variable.
- You must ensure that the symbol used in the assembly statement is unique within the scope of the source file and is valid according to the assembler's requirements.
- Referencing an external symbol directly, without going through the operand list, is not supported.

**Related reference**

Variables in specified registers (IBM extension)

**Examples of inline assembly statements**

In the following example:

```
__asm("x DC F'0' ":"XL:DS:4"(x));
```

The contents of the instruction `x DC F'0'` will be inserted into the assembly file to define `x` directly. The constraint `XL:DS:4` indicates that the data size for this variable is 4.

The following is an example of an assembly statement using register pair constraints:

```
__asm ( " CLCL %0, %2" : "XL:RP:r:e"(s1), "r"(len1), "RP"(s2), "r"(len2));
```

In this example, `CLCL` is the data to be defined in the assembly code. `%0` and `%2` are the operands, which are to be substituted by the C expressions in the output/input operand fields. For the first two output operands, an even/odd register pair will be allocated; for the second two output operands, another even/odd register pair will be allocated. The `r` constraint indicates that a general purpose register is required. Within these restrictions, the compiler is free to choose any registers to substitute for `%0` and `%2`. 
Chapter 8. Functions

In the context of programming languages, the term *function* means an assemblage of statements used for computing an output value. The word is used less strictly than in mathematics, where it means a set relating input variables uniquely to output variables. Functions in C or C++ programs may not produce consistent outputs for all inputs, may not produce output at all, or may have side effects. Functions can be understood as user-defined operations, in which the parameters of the parameter list, if any, are the operands.

Information on functions include:
- Function declarations and definitions
- Function storage class specifiers
- Function specifiers
- Function return type specifiers
- Function declarators
- Function attributes (IBM extension)
- The main() function
- Function calls
- Default arguments in C++ functions
- Pointers to functions

Function declarations and definitions

The distinction between a function *declaration* and function *definition* is similar to that of a data declaration and definition. The declaration establishes the names and characteristics of a function but does not allocate storage for it, while the *definition* specifies the body for a function, associates an identifier with the function, and allocates storage for it. Thus, the identifiers declared in this example:

```c
float square(float x);
```

do not allocate storage.

The *function definition* contains a function declaration and the body of a function. The body is a block of statements that perform the work of the function. The identifiers declared in this example allocate storage; they are both declarations and definitions.

```c
float square(float x) {
  return x*x;
}
```

A function can be declared several times in a program, but all declarations for a given function must be compatible; that is, the return type is the same and the parameters have the same type. However, a function can only have one definition. Declarations are typically placed in header files, while definitions appear in source files.

Function declarations

A function identifier preceded by its return type and followed by its parameter list is called a *function declaration* or *function prototype*. The prototype informs the compiler of the format and existence of a function prior to its use. The compiler checks for mismatches between the parameters of a function call and those in the function declaration. The compiler also uses the declaration for argument type checking and argument conversions.
Implicit declaration of functions is not allowed: you must explicitly declare every function before you can call it.

If a function declaration is not visible at the point at which a call to the function is made, the compiler assumes an implicit declaration of `extern int func();` However, for conformance to C99, you should explicitly prototype every function before making a call to it.

The elements of a declaration for a function are as follows:

- "Function storage class specifiers" on page 189, which specify linkage
- "Function return type specifiers" on page 198, which specify the data type of a value to be returned
- "Function specifiers" on page 191, which specify additional properties for functions
- "Function declarators" on page 200, which include function identifiers as well as lists of parameters

All function declarations have the form:

**Function declaration syntax**

```
storage_class_specifier function_specifier return_type_specifier function_declarator ;
```

**Note:** When `function_declarator` incorporates a trailing return type, `return_type_specifier` must be `auto`. For more information about trailing return type, see "Trailing return type (C++0x)" on page 202.

**Function definitions**

The elements of a function definition are as follows:

- "Function storage class specifiers" on page 189, which specify linkage
- "Function return type specifiers" on page 198, which specify the data type of a value to be returned
- "Function specifiers" on page 191, which specify additional properties for functions
- "Function declarators" on page 200, which include function identifiers as well as lists of parameters
- The function body, which is a braces-enclosed series of statements representing the actions that the function performs
- Constructor-initializers, which are used only in constructor functions declared in classes; they are described in "Constructors" on page 304.
- Try blocks, which are used in class functions; they are described in "try blocks" on page 371.

Function definitions take the following form:

**Function definition syntax (C only)**

```
storage_class_specifier function_specifier return_type_specifier

function_declarator (function body)
```

C++ Constructor-initializers, which are used only in constructor functions declared in classes; they are described in "Constructors" on page 304.

C++ Try blocks, which are used in class functions; they are described in "try blocks" on page 371.
Function definition syntax (C++ only)

```
storage_class_specifier [ function_specifier  ] return_type_specifier function_declarator
```

```
: constructor-initializer { function body } try-block
```

C++0x

Note: When `function_declarator` incorporates a trailing return type, `return_type_specifer` must be `auto`. For more information about trailing return type, see “Trailing return type (C++0x)” on page 202.

C++0x

Examples of function declarations

The following code fragments show several function declarations (or prototypes). The first declares a function `f` that takes two integer arguments and has a return type of `void`:

```
void f(int, int);
```

This fragment declares a pointer `p1` to a function that takes a pointer to a constant character and returns an integer:

```
int (*p1) (const char*);
```

The following code fragment declares a function `f1` that takes an integer argument, and returns a pointer to a function that takes an integer argument and returns an integer:

```
int (*f1(int)) (int);
```

Alternatively, a typedef can be used for the complicated return type of function `f1`:

```
typedef int f1_return_type(int);
f1_return_type* f1(int);
```

The following declaration is of an external function `f2` that takes a constant integer as its first argument, can have a variable number and variable types of other arguments, and returns type `int`:

```
int extern f2(const int, ...); /* C version */
int extern f2(const int ...); // C++ version
```

Function `f6` is a `const` class member function of class `X`, takes no arguments, and has a return type of `int`:

```
class X
{
public:
    int f6() const;
};
```

Function `f4` takes no arguments, has return type `void`, and can throw class objects of types `X` and `Y`.

```
class X;
class Y;
// ...
void f4() throw(X,Y);
```
Examples of function definitions

The following example is a definition of the function `sum`:
```
int sum(int x, int y)
{
    return(x + y);
}
```

The function `sum` has external linkage, returns an object that has type `int`, and has two parameters of type `int` declared as `x` and `y`. The function body contains a single statement that returns the sum of `x` and `y`.

The following function `set_date` declares a pointer to a structure of type `date` as a parameter. `date_ptr` has the storage class specifier `register`.
```
void set_date(register struct date *date_ptr)
{
    date_ptr->mon = 12;
    date_ptr->day = 25;
    date_ptr->year = 87;
}
```

Compatible functions (C only)

For two function types to be compatible, they must meet the following requirements:
- They must agree in the number of parameters (and use of ellipsis).
- They must have compatible return types.
- The corresponding parameters must be compatible with the type that results from the application of the default argument promotions.

The composite type of two function types is determined as follows:
- If one of the function types has a parameter type list, the composite type is a function prototype with the same parameter type list.
- If both function types have parameter type lists, the composite type of each parameter is determined as follows:
  - The composite of parameters of different rank is the type that results from the application of the default argument promotions.
  - The composite of parameters with array or function type is the adjusted type.
  - The composite of parameters with qualified type is the unqualified version of the declared type.

For example, for the following two function declarations:
```
int f(int (*)(char *), double (*)(*)[3]);
int f(int (*)(char *), double (*)(*)[]);
```

The resulting composite type would be:
```
int f(int (*)(char *), double (*)(*)[3]);
```

If the function declarator is not part of the function declaration, the parameters may have incomplete type. The parameters may also specify variable length array types by using the `[*]` notation in their sequences of declarator specifiers. The following are examples of compatible function prototype declarators:
```
double maximum(int n, int m, double a[n][m]);
double maximum(int n, int m, double a[ ][*]);
double maximum(int n, int m, double a[ ][*][]);
double maximum(int n, int m, double a[ ][*][m]);
```
**Multiple function declarations (C++ only)**

All function declarations for a particular function must have the same number and type of parameters, and must have the same return type.

These return and parameter types are part of the function type, although the default arguments and exception specifications are not.

If a previous declaration of an object or function is visible in an enclosing scope, the identifier has the same linkage as the first declaration. However, a variable or function that has no linkage and later declared with a linkage specifier will have the linkage you have specified.

For the purposes of argument matching, ellipsis and linkage keywords are considered a part of the function type. They must be used consistently in all declarations of a function. If the only difference between the parameter types in two declarations is in the use of typedef names or unspecified argument array bounds, the declarations are the same. A const or volatile type qualifier is also part of the function type, but can only be part of a declaration or definition of a nonstatic member function.

If two function declarations match in both return type and parameter lists, then the second declaration is treated as redeclaration of the first. The following example declares the same function:

```c++
int foo(const string &bar);
int foo(const string &);
```

Declaring two functions differing only in return type is not valid function overloading, and is flagged as a compile-time error. For example:

```c++
void f();
int f();   // error, two definitions differ only in return type
int g()
{
  return f();
}
```

“Overloading functions” on page 231

---

**Function storage class specifiers**

For a function, the storage class specifier determines the linkage of the function. By default, function definitions have external linkage, and can be called by functions defined in other files. An exception is inline functions, which are treated by default as having internal linkage; see “Linkage of inline functions” on page 192 for more information.

A storage class specifier may be used in both function declarations and definitions. The only storage class options for functions are:

- **static**
- **extern**

**The static storage class specifier**

A function declared with the static storage class specifier has internal linkage, which means that it may be called only within the translation unit in which it is defined.
The static storage class specifier can be used in a function declaration only if it is at file scope. You cannot declare functions within a block as static.

> C++ This use of static is deprecated in C++. Instead, place the function in the unnamed namespace.

Related reference
- Internal linkage on page 7
- Chapter 9, "Namespaces (C++ only)," on page 221

The extern storage class specifier

A function that is declared with the extern storage class specifier has external linkage, which means that it can be called from other translation units. The keyword extern is optional; if you do not specify a storage class specifier, the function is assumed to have external linkage.

> C++ In z/OS XL C++, an extern declaration cannot appear in class scope.

> C++ In z/OS XL C++, you can use the extern keyword with arguments that specify the type of linkage.

extern function storage class specifier syntax

```
extern "linkage_specification"
```

where linkage_specification can be any of the following:

- builtin
- C
- C++
- COBOL
- FORTRAN
- OS
- OS_DOWNSTACK
- OS_NOSTACK
- OS_UPSTACK
- PLI

For an explanation of these options, see the descriptions in "#pragma linkage (C only)" on page 443.

The following fragments illustrate the use of extern "C":

```c
extern "C" int cf(); //declare function cf to have C linkage
extern "C" int (*c_fp)(); //declare a pointer to a function, called c_fp, which has C linkage
extern "C" {
    typedef void(*cfp_T)(); //create a type pointer to function with C linkage
    void cfn(); //create a function with C linkage
    void (*cfp)(); //create a pointer to a function, with C linkage
}
```

Linkage compatibility affects all C library functions that accept a user function pointer as a parameter, such as qsort. Use the extern "C" linkage specification to ensure that the declared linkages are the same. The following example fragment uses extern "C" with qsort.
#include <stdlib.h>

// function to compare table elements
extern "C" int TableCmp(const void *, const void *); // C linkage
extern void * GenTable(); // C++ linkage

int main() {
    void *table;
    table = GenTable(); // generate table
    qsort(table, 100, 15, TableCmp); // sort table, using TableCmp
    // and C library routine qsort();
}

While the C++ language supports overloading, other languages do not. The implications of this are:
- You can overload a function as long as it has C++ (default) linkage. Therefore, z/OS XL C++ allows the following series of statements:
  int func(int); // function with C++ linkage
  int func(char); // overloaded function with C++ linkage

  By contrast, you cannot overload a function that has non-C++ linkage:
  extern "FORTRAN"{int func(int);} // not allowed
  // compiler will issue an error message

  • Only one non-C++-linkage function can have the same name as overloaded functions. For example:
    int func(char);
    int func(int);
    extern "FORTRAN"{int func(int,int);} // not allowed since the parameter
    // list is the same as the one for
    // the second function with C++ linkage
    // compiler will issue an error message

  C++

Function specifiers

The available function specifiers for function definitions are:
- inline, which instructs the compiler to expand a function definition at the point of a function call.
- __cdecl, which sets linkage conventions for C++ function calls to C functions.
- _Export, which makes function definitions available to other modules.
- explicit, which can only be used for member functions of classes, and is described in "The explicit specifier" on page 319
- virtual, which can only be used for member functions of classes, and is described in "Virtual functions" on page 294
The inline function specifier

An inline function is one for which the compiler copies the code from the function definition directly into the code of the calling function rather than creating a separate set of instructions in memory. Instead of transferring control to and from the function code segment, a modified copy of the function body may be substituted directly for the function call. In this way, the performance overhead of a function call is avoided. Using the inline specifier is only a suggestion to the compiler that an inline expansion can be performed; the compiler is free to ignore the suggestion.

C Any function, with the exception of main, can be declared or defined as inline with the inline function specifier. Static local variables are not allowed to be defined within the body of an inline function.

C++ C++ functions implemented inside of a class declaration are automatically defined inline. Regular C++ functions and member functions declared outside of a class declaration, with the exception of main, can be declared or defined as inline with the inline function specifier. Static locals and string literals defined within the body of an inline function are treated as the same object across translation units; see [Linkage of inline functions] for details.

The following code fragment shows an inline function definition:
inline int add(int i, int j) { return i + j; }

The use of the inline specifier does not change the meaning of the function. However, the inline expansion of a function may not preserve the order of evaluation of the actual arguments.

The most efficient way to code an inline function is to place the inline function definition in a header file, and then include the header in any file containing a call to the function which you would like to inline.

Note: C To enable the inline function specifier in C, you must compile with c99 or the LANGLVL(STDC99) or LANGLVL(EXTC99) options.

Linkage of inline functions

C In C, inline functions are treated by default as having static linkage; that is, they are only visible within a single translation unit. Therefore, in the following example, even though function foo is defined in exactly the same way, foo in file a.c and foo in file b.c are treated as separate functions: two function bodies are generated, and assigned two different addresses in memory:

// a.c
#include <stdio.h>
inline int foo(){
    return 3;
}
void g(){
    printf("foo called from g: return value = %d, address = %p\n", foo(), &foo);
}

// b.c
#include <stdio.h>
inline int foo(){
    return 3;
}
void g();
int main() {
    printf("foo called from main: return value = %d, address = %p\n", foo(), &foo);
    g();
}

The output from the compiled program is:
foo called from main: return value = 3, address = 0x10000580
foo called from g: return value = 3, address = 0x10000500

Since inline functions are treated as having internal linkage, an inline function definition can co-exist with a regular, external definition of a function with the same name in another translation unit. However, when you call the function from the file containing the inline definition, the compiler may choose either the inline version defined in the same file or the external version defined in another file for the call; your program should not rely on the inline version being called. In the following example, the call to foo from function g could return either 6 or 3:

// a.c
#include <stdio.h>
inline int foo(){
    return 6;
}
void g(){
    printf("foo called from g: return value = %d\n", foo());
}

// b.c
#include <stdio.h>
int foo(){
    return 3;
}
void g();
int main() {
    printf("foo called from main: return value = %d\n", foo());
    g();
}

Similarly, if you define a function as extern inline, or redeclare an inline function as extern, the function simply becomes a regular, external function and is not inlined.

You must define an inline function in exactly the same way in each translation unit in which the function is used or called. Furthermore, if a function is defined as inline, but never used or called within the same translation unit, it is discarded by the compiler.

Nevertheless, in C++, inline functions are treated by default as having external linkage, meaning that the program behaves as if there is only one copy of the function. The function will have the same address in all translation units and each translation unit will share any static locals and string literals. Therefore, compiling the previous example gives the following output:
foo called from main: return value = 3, address = 0x10000580
foo called from g: return value = 3, address = 0x10000580

Redefining an inline function with the same name but with a different function body is illegal; however, the compiler does not flag this as an error, but simply generates a function body for the version defined in the
first file entered on the compilation command line, and discards the others. Therefore, the following example, in which inline function foo is defined differently in two different files, may not produce the expected results:

```c
// a.C
#include <stdio.h>
inline int foo(){
    return 6;
}

void g() {
    printf("foo called from g: return value = %d, address = %p\n", foo(), &foo);
}

// b.C
#include <stdio.h>
inline int foo(){
    return 3;
}

void g();

int main() {
    printf("foo called from main: return value = %d, address = %p\n", foo(), &foo);
    g();
}
```

When compiled with the command `xlc++ a.C b.C`, the output is:

```
foo called from main: return value = 6, address = 0x10001640
foo called from g: return value = 6, address = 0x10001640
```

The call to foo from main does not use the inline definition provided in b.C, but rather calls foo as a regular external function defined in a.C. It is your responsibility to ensure that inline function definitions with the same name match exactly across translation units, to avoid unexpected results.

Because inline functions are treated as having external linkage, any static local variables or string literals that are defined within the body of an inline function are treated as the same object across translation units. The following example demonstrates this:

```c
// a.C
#include <stdio.h>
inline int foo(){
    static int x = 23;
    printf("address of x = %p\n", &x);
    x++;
    return x;
}

void g() {
    printf("foo called from g: return value = %d\n", foo());
}

// b.C
#include <stdio.h>
inline int foo()
```

194   z/OS V1R13.0 XL C/C++ Language Reference
```c
{ static int x=23;
 printf("address of x = %p\n", &x);
 x++;
 return x;
}

void g();

int main() {
 printf("foo called from main: return value = %d\n", foo());
g();
}

The output of this program shows that x in both definitions of foo is indeed the same object:
address of x = 0x10011d5c
foo called from main: return value = 24
address of x = 0x10011d5c
foo called from g: return value = 25

If you want to ensure that each instance of function defined as inline is treated as a separate function, you can use the static specifier in the function definition in each translation unit, or compile with the -qstaticinline option. Note, however, that static inline functions are removed from name lookup during template instantiation, and are not found.

The __cdecl function specifier (C++ only)

You can use the __cdecl keyword to set linkage conventions for function calls in C++ applications. The __cdecl keyword instructs the compiler to read and write a parameter list by using C linkage conventions.

To set the __cdecl calling convention for a function, place the linkage keyword immediately before the function name or at the beginning of the declarator. For example:

```c
void __cdecl f();
char (__cdecl *fp) (void);
```

z/OS XL C++ allows the __cdecl keyword on member functions and nonmember functions. These functions can be static or nonstatic. It also allows the keyword on pointer-to-member function types and the typedef specifier.

Note: The compiler accepts both _cdecl and __cdecl (both single and double underscore).

Following is an example:

```c
// C++ nonmember functions
void _cdecl f1();
static void _cdecl f2();

// pointer to member function type
char (_cdecl *A::*mp) (void);

// typedef
typedef void (* _cdecl void_fcn)(int);

// C++ member functions
class A {
 public:
  void _cdecl func();
  static void _cdecl func1();
};
```
The \_cdecl linkage keyword only affects parameter passing; it does not prevent function name mangling. Therefore, you can still overload functions with non-default linkage. Note that you only acquire linkage by explicitly using the \_cdecl keyword. It overrides the linkage that it inherits from an extern "linkage" specification.

Following is an example:

```c
void \_cdecl foo(int); // C linkage with name mangled
void \_cdecl foo(char) // overload foo() with char is OK

void foo(int(*)());
// overload on linkage of function
void foo(int (__cdecl *)(()));
//pointer parameter is OK
extern "C++" {
    void \_cdecl foo(int);
    // foo() has C linkage with name mangled
}

extern "C" {
    void \_cdecl foo(int);
    // foo() has C linkage with name mangled
}
```

If the function is redeclared, the linkage keyword must appear in the first declaration; otherwise an error message is issued. Following are two examples:

```c
int c_cf();
int \_cdecl c_cf();
// Error 1251. The previous declaration did not have a linkage specification
int \_cdecl c_cf();
int c_cf();
// OK, the linkage is inherited from the first declaration
```

**Example of \_cdecl use**

The following example illustrates how you can use \_cdecl to pass in a C parameter list from C++ code to a C function:

```c
// C++ Application: passing a C++ function pointer to a C function
#include <stdio.h>

// C++ function declared with C calling convention
void \_cdecl callcxx() {
    printf(" I am a C++ function\n");
}
```
// declare a function pointer with __cdecl linkage
void (__cdecl *p1)();

// declare an extern C function,
// accepting a __cdecl function pointer
extern "C" {
    void CALLC(void (__cdecl *pp)());
}

// assign the function pointer to a __cdecl function
int main() {
    p1 = callcxx;

    // call the C function with the __cdecl function pointer
    CALLC(p1);
}

/*-----------------------------------------------------------------*/
/* C source file */
/*-----------------------------------------------------------------*/
/* */
/* C Routine: receiving a function pointer with C linkage */
/* */
/* */
#include <stdio.h>
extern void CALLC(void (*pp)());
    printf(" I am a C function\n");
    (*pp)(); // call the function passed in
}

The _Export function specifier (C++ only)

Use the _Export keyword with a function name to declare that it is to be exported (made available to other modules). You must define the function in the same translation unit in which you use the _Export keyword. For example:

```
int _Export anthony(float);
```

The above statement exports the function anthony, if you define the function within the translation unit.

The _Export keyword must immediately precede the function name. If the _Export keyword is repeated in a declaration, z/OS XL C++ issues a warning when you specify the INFO(GEN) option.

If you apply the _Export keyword to a class, the z/OS XL C++ compiler automatically exports all members of the class, whether static, public, private, or protected. However, if you want it to apply to individual class members, then you must apply it to each member that can be referenced. The following class definitions demonstrate this.

```
class A {
public:
    int iii() {
        printf("Hi from A::iii()\n");
        aaa();
        printf("Call to A::ccc() returned %c\n", ccc());
        return 88;
    }
static void _Export sss();
protected:
    void _Export aaa();
private:
    char _Export ccc();
```
class _Export B {
    public:
        int iii() {
            printf("Hi from B::iii()\n");
            aaa();
            printf("Call to B::ccc() returned %c\n", ccc());
            return 99;
        }
        static void sss();
    protected:
        void _Export aaa();
    private:
        char _Export ccc();
};

In the example below, both X::Print() and X::GetNext() will be exported.
    class _Export X {
    public:
        ... void static Print();
        int GetNext();
        ...
    };
    void X:: static Print() {
        ...
    } int X::GetNext() {
        ...
    }

The above examples demonstrate that you can either export specific members of a class or the entire class itself. Note that the _Export keyword can be applied to class tags in nested class declarations.

Function return type specifiers

The result of a function is called its return value and the data type of the return value is called the return type.

- **C++** Every function declaration and definition must specify a return type, whether or not it actually returns a value.

- **C** If a function declaration does not specify a return type, the compiler assumes an implicit return type of int. However, for conformance to C99, you should specify a return type for every function declaration and definition, whether or not the function returns int.

A function may be defined to return any type of value, except an array type or a function type; these exclusions must be handled by returning a pointer to the array or function. When a function does not return a value, void is the type specifier in the function declaration and definition.

A function cannot be declared as returning a data object having a volatile or const type, but it can return a pointer to a volatile or const object.

A function can have a return type that is a user-defined type. For example:
enum count {one, two, three};
enum count counter();

- **C** The user-defined type may also be defined within the function declaration.  
**C++** The user-defined type may not be defined within the function declaration.

```
enum count {one, two, three} counter(); // legal in C
enum count {one, two, three} counter(); // error in C++
```

- **C++** References can also be used as return types for functions. The reference returns the lvalue of the object to which it refers.

**Related reference**

"Type specifiers" on page 49

**Function return values**

- **C** If a function is defined as having a return type of `void`, it should not return a value.  
**C++** In C++, a function which is defined as having a return type of `void`, or is a constructor or destructor, *must* not return a value.

- **C** If a function is defined as having a return type other than `void`, it should return a value. Under compilation for strict C99 conformance, a function defined with a return type *must* include an expression containing the value to be returned.

- **C++** A function defined with a return type *must* include an expression containing the value to be returned.

When a function returns a value, the value is returned via a `return` statement to the caller of the function, after being implicitly converted to the return type of the function in which it is defined. The following code fragment shows a function definition including the `return` statement:

```
int add(int i, int j)
{
    return i + j; // return statement
}
```

The function `add()` can be called as shown in the following code fragment:

```
int a = 10,
    b = 20;
int answer = add(a, b); // answer is 30
```

In this example, the `return` statement initializes a variable of the returned type. The variable `answer` is initialized with the `int` value 30. The type of the returned expression is checked against the returned type. All standard and user-defined conversions are performed as necessary.

Each time a function is called, new copies of its variables with automatic storage are created. Because the storage for these automatic variables may be reused after the function has terminated, a pointer or reference to an automatic variable should not be returned.  
**C++** If a class object is returned, a temporary object may be created if the class has copy constructors or a destructor.
Function declarators

Function declarators consist of the following elements:

- An identifier, or name
- Parameter declarations, which specify the parameters that can be passed to the function in a function call
- C++ Exception declarations, which include throw expressions; exception specifications are described in Chapter 16, “Exception handling (C++ only),” on page 371.
- C++ The type qualifiers const and volatile, which are used only in class member functions; they are described in “Constant and volatile member functions” on page 258.

Function declarator syntax (C only)

Function declarator syntax (C++ only)

Parameter declarations

The function declarator includes the list of parameters that can be passed to the function when it is called by another function, or by itself.

C++ In C++, the parameter list of a function is referred to as its signature. The name and signature of a function uniquely identify it. As the word itself suggests, the function signature is used by the compiler to distinguish among the different instances of overloaded functions.
An empty argument list in a function declaration or definition indicates a function that takes no arguments. To explicitly indicate that a function does not take any arguments, you can declare the function in two ways: with an empty parameter list, or with the keyword `void`:

```cpp
int f(void);
int f();
```

An empty argument list in a function definition indicates that a function that takes no arguments. An empty argument list in a function declaration indicates that a function may take any number or type of arguments. Thus,

```c
int f()
{
...
}
```

indicates that function `f` takes no arguments. However,

```c
int f();
```

simply indicates that the number and type of parameters is not known. To explicitly indicate that a function does not take any arguments, you should define the function with the keyword `void`.

An ellipsis at the end of the parameter specifications is used to specify that a function has a variable number of parameters. The number of parameters is equal to, or greater than, the number of parameter specifications.

```c
int f(int, ...);
```

The comma before the ellipsis is optional. In addition, a parameter declaration is not required before the ellipsis.

At least one parameter declaration, as well as a comma before the ellipsis, are both required in C.

### Parameter types

In a function declaration, or prototype, the type of each parameter must be specified. In the function definition, the type of each parameter must also be specified. In the function definition, if the type of a parameter is not specified, it is assumed to be `int`.

A variable of a user-defined type may be declared in a parameter declaration, as in the following example, in which `x` is declared for the first time:

```c
struct X { int i; };
void print(struct X x);
```

The user-defined type can also be defined within the parameter declaration. The user-defined type can not be defined within the parameter declaration.

```c
void print(struct X { int i; } x); // legal in C
void print(struct X { int i; } x); // error in C++
```

### Parameter names

In a function definition, each parameter must have an identifier. In a function declaration, or prototype, specifying an identifier is optional. Thus, the following example is legal in a function declaration:

```c
int func(int,long);
```

The following constraints apply to the use of parameter names in function declarations:
Two parameters cannot have the same name within a single declaration.

If a parameter name is the same as a name outside the function, the name outside the function is hidden and cannot be used in the parameter declaration. In the following example, the third parameter name `intersects` is meant to have enumeration type `subway_line`, but this name is hidden by the name of the first parameter. The declaration of the function `subway()` causes a compile-time error because `subway_line` is not a valid type name because the first parameter name `subway_line` hides the namespace scope `enum` type and cannot be used again in the second parameter.

```c
enum subway_line {yonge,
    university, spadina, bloor};
int subway(char * subway_line, int stations,
    subway_line intersects);
```

### Static array indices in function parameter declarations (C only)

Except in certain contexts, an unsubscripted array name (for example, `region` instead of `region[4]`) represents a pointer whose value is the address of the first element of the array, provided that the array has previously been declared. An array type in the parameter list of a function is also converted to the corresponding pointer type. Information about the size of the argument array is lost when the array is accessed from within the function body.

To preserve this information, which is useful for optimization, you may declare the index of the argument array using the `static` keyword. The constant expression specifies the minimum pointer size that can be used as an assumption for optimizations. This particular usage of the `static` keyword is highly prescribed.

The keyword may only appear in the outermost array type derivation and only in function parameter declarations. If the caller of the function does not abide by these restrictions, the behavior is undefined.

The following examples show how the feature can be used.

```c
void foo(int arr [static 10]); /* arr points to the first of at least 10 ints */
void foo(int arr [const 10]); /* arr is a const pointer */
void foo(int arr [static const i]); /* arr points to at least i ints; i is computed at run time. */
void foo(int arr [const static i]); /* alternate syntax to previous example */
void foo(int arr [const]); /* const pointer to int */
```

### Trailing return type (C++0x)

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

The trailing return type feature removes a C++ limitation where the return type of a function template cannot be generalized if the return type depends on the types of the function arguments. For example, a
and b are arguments of a function template `multiply(const A &a, const B &b)`, where a and b are of arbitrary types. Without the trailing return type feature, you cannot declare a return type for the `multiply` function template to generalize all the cases for a*b. With this feature, you can specify the return type after the function arguments. This resolves the scoping problem when the return type of a function template depends on the types of the function arguments.

### Trailing return type syntax

```c++
function_identifier (parameter_declaration, cv_qualifier) -> return_type
```

### Notes:

- This syntax is not the one for a function declaration or definition. The auto placeholder occurs in the syntax for declarations and definitions where they specify `return_type_specifier`.
- As with function declarators without a trailing return type, this syntax might be used to declare a pointer or reference to function.

To use the trailing return type feature, declare a generic return type with the `auto` keyword before the function identifier, and specify the exact return type after the function identifier. For example, use the `decltype` keyword to specify the exact return type.

```c++
// Trailing return type is used to represent
// a fully generic return type for a+b.
template <typename FirstType, typename SecondType>
auto add(FirstType a, SecondType b) -> decltype(a + b){
  return a + b;
}
```

```c++
int main(){
  // The first template argument is of the integer type, and
  // the second template argument is of the character type.
  add(1, 'A');

  // Both the template arguments are of the integer type.
  add(3, 5);
}
```

### Notes:

- When a trailing return type is used, the placeholder return type must be `auto`. For example, the statement `auto *f() -> char` results in a compile-time error, because `auto *` is not allowed as the placeholder return type.
- The `auto` type specifier can be used with a function declarator with a trailing return type. Otherwise, the `auto` type specifier is used in accordance to the auto type deduction feature. For more information about auto type deduction, see "The auto type specifier (C++0x)" on page 67. Because a function declaration cannot have an initializer as required for auto type deduction, the auto type specifier cannot be used in a function declaration without a trailing return type. For declarations of pointers and references to functions, the auto type specifier can be used with either a corresponding trailing return type or an initializer. For details of pointers and references to functions, see "Pointers to functions" on page 218.
- The return type of a function cannot be any of the following types:
  - Function
  - Array
• The return type of a function cannot define any of the following types:
  – struct
  – class
  – union
  – enum

However, the return type can be any of these types if the type is not defined in the function declaration.

In addition, this feature makes your program more compact and elegant in cases where functions have complicated return types. Without this feature, programs might be complicated and error prone. See the following example:

```cpp
template <class A, class B> class K{
  public:
    int i;
};
K<int, double> (*(*bar())())() {
  return 0;
}
```

You can use the trailing return type feature to make the code compact. See the following example:

```cpp
template <class A, class B> class K{
  public:
    int i;
};
auto bar() -> decltype(auto)(*())()->K<int, double>(*()){
  return 0;
}
```

This feature can also be used for member functions of classes. In the following example, the program is concise because the return type of the member function `bar` does not need to be qualified after using a trailing return type:

```cpp
struct A{
  typedef int ret_type;
  auto bar() -> ret_type;
};
// ret_type is not qualified
auto A::bar() -> ret_type{
  return 0;
}
```

Another use of this feature is in writing perfect forwarding functions. That is, the forwarding function calls another function, and the return type of the forwarding function is the same as that of the called function. See the following example:

```cpp
double number (int a){
  return double(a);
}
int number(double b){
  return int(b);
}

template <class A>
auto wrapper(A a) -> decltype(number(a)){
  return number(a);
}
```
int main()
{
    // The return value is 1.000000.
    wrapper(1);

    // The return value is 1.
    wrapper(1.5);
}

In this example, the wrapper function and the number function have the same return type.

Function attributes (IBM extension)

Function attributes are extensions implemented to enhance the portability of programs developed with GNU C. Specifiable attributes for functions provide explicit ways to help the compiler optimize function calls and to instruct it to check more aspects of the code. Others provide additional functionality.

A function attribute is specified with the keyword __attribute__ followed by the attribute name and any additional arguments the attribute name requires. A function __attribute__ specification is included in the declaration or definition of a function. The syntax takes the following forms:

Function attribute syntax: function declaration

```plaintext
_function declarator__attribute__((attribute_name(attribute_name...)));
```

Function attribute syntax: function definition (C only)

```plaintext
__attribute__((attribute_name(attribute_name...)))function_declarator({function body});
```

The function attribute in a function declaration is always placed after the declarator, including the parenthesized parameter declaration:

```c
/* Specify the attribute on a function prototype declaration */
void f(int i, int j) __attribute__((individual_attribute_name));
void f(int i, int j) {}
```

Due to ambiguities in parsing old-style parameter declarations, a function definition must have the attribute specification precede the declarator:

```c
int __attribute__((individual_attribute_name)) foo(int i) {}
```
A function attribute specification using the form `__attribute_name__` (that is, the attribute name with double underscore characters leading and trailing) reduces the likelihood of a name conflict with a macro of the same name.

**C** The `amode31`|`amode64` function attribute and `armode`|`noarmode` function attribute are supported.

**Related reference**

“Variable attributes (IBM extension)” on page 105

**The amode31 | amode64 function attribute (C only)**

When the METAL compiler option is in effect, it is possible for the application to switch between 31-bit and 64-bit addressing modes during function calls and returns. You can use the `amode31` or `amode64` function attribute to identify the addressing mode of the called function.

### amode31 | amode64 function attribute syntax

```
__attribute__((amode31 | amode64))
```

The following example declares the function `foo` to be in AMODE 64 mode:

```c
void foo() __attribute__((amode64));
```

For more information on the METAL compiler option, see the METAL compiler option description in *z/OS XL C/C++ User’s Guide*. For more information on AMODE switching, see *z/OS Metal C Programming Guide and Reference*.

**The armode | noarmode function attribute (C only)**

When the METAL compiler option is in effect, you can use the `armode` function attribute to specify whether or not a given function is to operate in access-register (AR) mode. AR mode allows a C function to access multiple additional data spaces, and manipulate more data in memory.

### armode function attribute syntax

```
__attribute__((armode))
```

The following example declares the function `foo` to be in AR mode:

```c
void foo() __attribute__((armode));
```

The attribute overrides the default setting of the ARMODE compiler option for the specified function. Note that this attribute is only supported when the METAL compiler option is in effect.

For more information on ARMODE and METAL compiler options, see ARMODE and METAL compiler options in the *z/OS XL C/C++ User’s Guide*.

**Related reference**

“The armode | noarmode type attribute (C only)” on page 82

“The __far type qualifier (C only)” on page 77

**gnu_inline**

The `gnu_inline` attribute instructs the compiler to modify the inlining behavior of a function. When this function attribute is used, the compiler imitates traditional gnu89 inline behavior.
This function attribute is only enabled if used in conjunction with an inline keyword (__inline__, inline, __inline, etc.).

**gnu_inline function attribute syntax**

```
inline __attribute__((gnu_inline))
```

**Note:** The behavior of the gnu_inline function attribute is the same when used in conjunction with either the inline or __inline__ keywords.

The traditional gnu90 inline semantics are as follows:

**C**

```c
extern gnu_inline:
extern inline __attribute__((gnu_inline)) foo() {...};
```

This definition of foo is used only for inlining. It is not compiled as a standalone function.

```c
static gnu_inline:
static inline __attribute__((gnu_inline)) foo() {...};
```

If the function is generated, it is generated with internal linkage.

```c
plain gnu_inline:
inline __attribute__((gnu_inline)) foo() {...};
```

The definition is used for inlining when possible. It is compiled as a standalone function (emitted as a strong definition) and emitted with external linkage.

**C++**

```cpp
extern gnu_inline:
[extern] inline __attribute__((gnu_inline)) foo() {...};
```

This definition of foo is used only for inlining. It is not compiled as a standalone function. Note that member functions (including static ones and ones with no linkage) marked with function attribute gnu_inline has "extern" behavior.

```cpp
static gnu_inline:
static inline __attribute__((gnu_inline)) foo() {...};
```

If the function is generated, it is generated with internal linkage. Note that static behavior only applies to non-member static functions.

The gnu_inline attribute can be specified inside double parentheses with keyword __attribute__ in a function declaration. See the following example.

```c
inline int foo() __attribute__((gnu_inline));
```

As with other GCC function attributes, the double underscores on the attribute name are optional. The gnu_inline attribute should be used with a function that is also declared with the inline keyword.
malloc

With the function attribute malloc, you can instruct the compiler to treat a function as if any non-NULL pointer it returns cannot alias any other valid pointers. This type of function (such as malloc and calloc) has this property, hence the name of the attribute. As with all supported attributes, malloc will be accepted by the compiler without requiring any particular option or language level.

The malloc function attribute can be specified inside double parentheses via keyword __attribute__ in a function declaration.

malloc function attribute syntax

```c
__attribute__((malloc))
```

As with other GCC function attributes, the double underscores on the attribute name are optional.

Note:

- Do not use this function attribute unless you are sure that the pointer returned by a function points to unique storage. Otherwise, optimizations performed might lead to incorrect behavior at run time.
- If the function does not have a pointer or C++ reference return type but it is marked with the function attribute malloc, a warning is emitted, and the attribute is ignored.

Example

A simple testcase that should be optimized when attribute malloc is used:

```c
#include <stdlib.h>
#include <stdio.h>
int a;
void* my_malloc(int size) __attribute__((malloc)) {
    void* p = malloc(size);
    if (!p) {
        printf("my_malloc: out of memory!
");
        exit(1);
    }
    return p;
}

int main() {
    int* x = &a;
    int* p = (int*) my_malloc(sizeof(int));
    *x = 0;
    *p = 1;
    if (*x) printf("This printf statement to be detected as unreachable
        and discarded during compilation process\n");
    return 0;
}
```

used

When a function is referenced only in inline assembly, you can use the used function attribute to instruct the compiler to emit the code for the function even if it appears that the function is not referenced.

The used function attribute can be specified inside double parentheses via keyword __attribute__ in a function declaration, for example, int foo() __attribute__((used)); As with other GCC function attributes, the double underscores on the attribute name are optional.

used function attribute syntax
If the function attribute \texttt{gnu\_inline} is specified in such a way that the function is discarded, and is specified together with the function attribute \texttt{used}, the \texttt{gnu\_inline} attribute wins, and the function definition is discarded.

\section*{The main() function}

When a program begins running, the system calls the function \texttt{main}, which marks the entry point of the program. By default, \texttt{main} has the storage class \texttt{extern}. Every program must have one function named \texttt{main}, and the following constraints apply:

\begin{itemize}
  \item No other function in the program can be called \texttt{main}.
  \item \texttt{main} cannot be defined as \texttt{inline} or \texttt{static}.
  \item \texttt{C++} main cannot be called from within a program.
  \item \texttt{C++} The address of \texttt{main} cannot be taken.
  \item \texttt{C++} The \texttt{main} function cannot be overloaded.
\end{itemize}

The function \texttt{main} can be defined with or without parameters, using any of the following forms:

\begin{verbatim}
int main (void)
int main ( )
int main(int argc, char *argv[])
int main (int argc, char ** argv)
\end{verbatim}

Although any name can be given to these parameters, they are usually referred to as \texttt{argc} and \texttt{argv}. The first parameter, \texttt{argc} (argument count) is an integer that indicates how many arguments were entered on the command line when the program was started. The second parameter, \texttt{argv} (argument vector), is an array of pointers to arrays of character objects. The array objects are null-terminated strings, representing the arguments that were entered on the command line when the program was started.

The first element of the array, \texttt{argv[0]}, is a pointer to the character array that contains the program name or invocation name of the program that is being run from the command line. \texttt{argv[1]} indicates the first argument passed to the program, \texttt{argv[2]} the second argument, and so on.

The following example program \texttt{backward} prints the arguments entered on a command line such that the last argument is printed first:

\begin{verbatim}
#include <stdio.h>
int main(int argc, char *argv[])
{
  while (--argc > 0)
    printf("%s ", argv[argc]);
  printf("\n");
}
\end{verbatim}

Invoking this program from a command line with the following:

\begin{verbatim}
backward string1 string2
\end{verbatim}

gives the following output:

\begin{verbatim}
string2 string1
\end{verbatim}

The arguments \texttt{argc} and \texttt{argv} would contain the following values:
<table>
<thead>
<tr>
<th>Object</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>argc</td>
<td>3</td>
</tr>
<tr>
<td>argv[0]</td>
<td>pointer to string &quot;backward&quot;</td>
</tr>
<tr>
<td>argv[1]</td>
<td>pointer to string &quot;string1&quot;</td>
</tr>
<tr>
<td>argv[2]</td>
<td>pointer to string &quot;string2&quot;</td>
</tr>
<tr>
<td>argv[3]</td>
<td>NULL</td>
</tr>
</tbody>
</table>

**Note:** See z/OS XL C/C++ Programming Guide for details about receiving the parameter list (argv) in C main, preparing your main function to receive parameters, and on C and C++ parameter passing considerations.

**Related reference**

- "The inline function specifier" on page 192
- "The static storage class specifier" on page 45
- "Function calls" on page 211

**Command-line arguments**

z/OS XL C/C++ treats arguments that you enter on the command line differently in different environments. The following lists how argv and argc are handled.

The maximum allowable length of a command-line argument for z/OS Language Environment is 64K.

**Under z/OS batch**
- argc: Returns the number of strings in the argument line
- argv[0]: Returns the program name in uppercase
- argv[1 to n]: Returns the arguments as you enter them

**Under IBM IMS™**
- argc: Returns 1
- argv[0]: Is a null pointer

**Under IBM CICS®**
- argc: Returns 1
- argv[0]: Returns the transaction ID

**Under TSO command**
- argc: Returns the number of strings in the argument line
- argv[0]: Returns the program name in uppercase
- argv[1 to n]: Arguments entered in uppercase are returned in lowercase. Arguments entered in mixed or lowercase are returned as entered.
**Under TSO call**

Without the ASIS option:

- `argc` Returns the number of strings in the argument line
- `argv` Returns the program name and arguments in lowercase

With the ASIS option:

- `argc` Returns the number of strings in the argument line
- `argv[0]` Returns the program name in uppercase
- `argv[1 to n]` Arguments entered in uppercase are returned in lowercase. Arguments entered in mixed or lowercase are returned as entered.

**Under z/OS UNIX System Services shell**

- `argc` Returns the number of strings in the argument line
- `argv[0]` Returns the program name as you enter it
- `argv[1 to n]` Returns the arguments exactly as you enter them

The only delimiter for the arguments that are passed to `main()` is white space. z/OS XL C/C++ uses commas passed to `main()` by JCL as arguments and not as delimiters.

The following example appends the comma to the 'one' when passed to `main()`.

```c
//FUNC EXEC PCGO,GPGM='FUNC',
//    PARM.GO=('one',
//    'two')
```

For more information on restrictions of the command-line arguments, refer to z/OS XL C/C++ User's Guide.

**Function calls**

After a function is declared and defined, it can be called from anywhere within the program: from within the `main` function, from another function, and even from itself. Calling the function involves specifying the function name, followed by the function call operator and any data values the function expects to receive. These values are the arguments for the parameters defined for the function. This process is called passing arguments to the function.

You can pass arguments to the called functions in three ways:

- **"Pass by value" on page 212**, which copies the value of an argument to the corresponding parameter in the called function;
- **"Pass by pointer" on page 213**, which passes a pointer argument to the corresponding parameter in the called function;
Pass by reference (C++ only) on page 213, which passes the reference of an argument to the corresponding parameter in the called function.

If a class has a destructor or a copy constructor that does more than a bitwise copy, passing a class object by value results in the construction of a temporary object that is actually passed by reference.

The compiler generates an error when a function argument is a class object and all of the following conditions are true:
- The class needs a copy constructor.
- The class does not have a user-defined copy constructor.
- A copy constructor cannot be generated for that class.

Pass by value

When you use pass-by-value, the compiler copies the value of an argument in a calling function to a corresponding non-pointer or non-reference parameter in the called function definition. The parameter in the called function is initialized with the value of the passed argument. As long as the parameter has not been declared as constant, the value of the parameter can be changed, but the changes are only performed within the scope of the called function only; they have no effect on the value of the argument in the calling function.

In the following example, main passes func two values: 5 and 7. The function func receives copies of these values and accesses them by the identifiers a and b. The function func changes the value of a. When control passes back to main, the actual values of x and y are not changed.

```c
#include <stdio.h>

void func (int a, int b)
{
    a = b;
    printf("In func, a = %d  b = %d\n", a, b);
}

int main(void)
{
    int x = 5, y = 7;
    func(x, y);
    printf("In main, x = %d  y = %d\n", x, y);
    return 0;
}
```

The output of the program is:

In func, a = 12 b = 7
In main, x = 5  y = 7
Pass by pointer

Pass-by-pointer means to pass a pointer argument in the calling function to the corresponding formal parameter of the called function. The called function can modify the value of the variable to which the pointer argument points.

The following example shows how arguments are passed by pointer:

```c
#include <stdio.h>

void swapnum(int *i, int *j) {
    int temp = *i;
    *i = *j;
    *j = temp;
}

int main(void) {
    int a = 10;
    int b = 20;
    swapnum(&a, &b);
    printf("A is %d and B is %d\n", a, b);
    return 0;
}
```

When the function `swapnum()` is called, the values of the variables `a` and `b` are exchanged because they are passed by pointer. The output is:

```
A is 20 and B is 10
```

When you use pass-by-pointer, a copy of the pointer is passed to the function. If you modify the pointer inside the called function, you only modify the copy of the pointer, but the original pointer remains unmodified and still points to the original variable.

The difference between pass-by-pointer and pass-by-value is that modifications made to arguments passed in by pointer in the called function have effect in the calling function, whereas modifications made to arguments passed in by value in the called function can not affect the calling function. Use pass-by-pointer if you want to modify the argument value in the calling function. Otherwise, use pass-by-value to pass arguments.

Related reference

“Pointers” on page 86

Pass by reference (C++ only)

Pass-by-reference means to pass the reference of an argument in the calling function to the corresponding formal parameter of the called function. The called function can modify the value of the argument by using its reference passed in.

The following example shows how arguments are passed by reference. The reference parameters are initialized with the actual arguments when the function is called.

```c
#include <stdio.h>

void swapnum(int &i, int &j) {
    int temp = i;
    i = j;
    j = temp;
}
```
int main(void) {
    int a = 10;
    int b = 20;
    swapnum(a, b);
    printf("A is \%d and B is \%d\n", a, b);
    return 0;
}

When the function swapnum() is called, the values of the variables a and b are exchanged because they are passed by reference. The output is:
A is 20 and B is 10

To modify a reference that is qualified by the const qualifier, you must cast away its constness with the const_cast operator. For example:
#include <iostream>
using namespace std;

void f(const int& x) {
    int& y = const_cast<int&>(x);
    ++y;
}

int main() {
    int a = 5;
    f(a);
    cout << a << endl;
}

This example outputs 6.

Pass-by-references is more efficient than pass-by-value, because it does not copy the arguments. The formal parameter is an alias for the argument. When the called function read or write the formal parameter, it is actually read or write the argument itself.

The difference between pass-by-reference and pass-by-value is that modifications made to arguments passed in by reference in the called function have effect in the calling function, whereas modifications made to arguments passed in by value in the called function can not affect the calling function. Use pass-by-reference if you want to modify the argument value in the calling function. Otherwise, use pass-by-value to pass arguments.

The difference between pass-by-reference and pass-by-pointer is that pointers can be NULL or reassigned whereas references cannot. Use pass-by-pointer if NULL is a valid parameter value or if you want to reassign the pointer. Otherwise, use constant or non-constant references to pass arguments.

Allocation and deallocation functions (C++ only)

You may define your own new operator or allocation function as a class member function or a global namespace function with the following restrictions:
• The first parameter must be of type std::size_t. It cannot have a default parameter.
• The return type must be of type void*.
• Your allocation function may be a template function. Neither the first parameter nor the return type may depend on a template parameter.
If you declare your allocation function with the empty exception specification `throw()`, your allocation function must return a null pointer if your function fails. Otherwise, your function must throw an exception of type `std::bad_alloc` or a class derived from `std::bad_alloc` if your function fails.

You may define your own `delete` operator or deallocation function as a class member function or a global namespace function with the following restrictions:

- The first parameter must be of type `void*`.
- The return type must be of type `void`.
- Your deallocation function may be a template function. Neither the first parameter nor the return type may depend on a template parameter.

The following example defines replacement functions for global namespace `new` and `delete`:

```cpp
#include <cstdio>
#include <cstdlib>
using namespace std;

void* operator new(size_t sz) {
    printf("operator new with %d bytes\n", sz);
    void* p = malloc(sz);
    if (p == 0) printf("Memory error\n");
    return p;
}

void operator delete(void* p) {
    if (p == 0) printf ("Deleting a null pointer\n");
    else {
        printf("delete object\n");
        free(p);
    }
}

struct A {
    const char* data;
    A() : data("Text String") { printf("Constructor of S\n"); }
    ~A() { printf("Destructor of S\n"); }
};

int main() {
    A* ap1 = new A;
    delete ap1;

    printf("Array of size 2:\n");
    A* ap2 = new A[2];
    delete[] ap2;
}
```

The following is the output of the above example:

```
operator
new with 40 bytes
new with 33 bytes
new with 4 bytes
Constructor of S
Destructor of S
delete object
Array of size 2:
operator new with 16 bytes
Constructor of S
Destructor of S
Destructor of S
delete object
```
Default arguments in C++ functions (C++ only)

You can provide default values for function parameters. For example:

```cpp
#include <iostream>
using namespace std;

int a = 1;
int f(int a) { return a; }
int g(int x = f(a)) { return x; }

int h() {
a = 2;
    int a = 3;
    return g();
}

int main() {
    cout << h() << endl;
}
```

This example prints 2 to standard output, because the a referred to in the declaration of g() is the one at file scope, which has the value 2 when g() is called.

The default argument must be implicitly convertible to the parameter type.

A pointer to a function must have the same type as the function. Attempts to take the address of a function by reference without specifying the type of the function will produce an error. The type of a function is not affected by arguments with default values.

The following example shows that default arguments are not considered part of a function's type. The default argument allows you to call a function without specifying all of the arguments, it does not allow you to create a pointer to the function that does not specify the types of all the arguments. Function f can be called without an explicit argument, but the pointer badpointer cannot be defined without specifying the type of the argument:

```cpp
int f(int = 0);
void g()
{
    int a = f(); // ok
    int b = f(); // ok, default argument used
}
int (*pointer)(int) = &f; // ok, type of f() specified (int)
int (*badpointer)() = &f; // error, badpointer and f have different types. badpointer must be initialized with a pointer to a function taking no arguments.
```

In this example, function f3 has a return type int, and takes an int argument with a default value that is the value returned from function f2:

```cpp
const int j = 5;
int f3( int x = f2(j) );
```
Restrictions on default arguments (C++ only)

Of the operators, only the function call operator and the operator `new` can have default arguments when they are overloaded.

Parameters with default arguments must be the trailing parameters in the function declaration parameter list. For example:

```cpp
g(void a = 1, int b = 2, int c) // error, leading defaults
g(int a = 1, int b, int c); // error, default in middle
```

Once a default argument has been given in a declaration or definition, you cannot redefine that argument, even to the same value. However, you can add default arguments not given in previous declarations. For example, the last declaration below attempts to redefine the default values for `a` and `b`:

```cpp
f(int a, int b=1, int c); // valid, add another default
g(int a=1, int b=1, int c=1); // error, redefined defaults
```

You can supply any default argument values in the function declaration or in the definition. Any parameters in the parameter list following a default argument value must have a default argument value specified in this or a previous declaration of the function.

You cannot use local variables in default argument expressions. For example, the compiler generates errors for both function `g()` and function `h()` below:

```cpp
void f(int a)
{
    int b=4;
    void g(int c=a); // Local variable "a" cannot be used here
    void h(int d=b); // Local variable "b" cannot be used here
}
```

Evaluation of default arguments (C++ only)

When a function defined with default arguments is called with trailing arguments missing, the default expressions are evaluated. For example:

```cpp
f(int a, int b = 2, int c = 3); // declaration
// ...
int a = 1;
f(a); // same as call f(a,2,3)
f(a,10); // same as call f(a,10,3)
f(a,10,20); // no default arguments
```

Default arguments are checked against the function declaration and evaluated when the function is called. The order of evaluation of default arguments is undefined. Default argument expressions cannot use other parameters of the function. For example:

```cpp
int f(int q = 3, int r = q); // error
```

The argument `r` cannot be initialized with the value of the argument `q` because the value of `q` may not be known when it is assigned to `r`. If the above function declaration is rewritten:
int q=5;
int f(int q = 3, int r = q); // error

The value of r in the function declaration still produces an error because the variable q defined outside of
the function is hidden by the argument q declared for the function. Similarly:

typedef double D;
int f(int D, int z = D(5.3) ); // error

Here the type D is interpreted within the function declaration as the name of an integer. The type D is
hidden by the argument D. The cast D(5.3) is therefore not interpreted as a cast because D is the name of
the argument not a type.

In the following example, the nonstatic member a cannot be used as an initializer because a does not exist
until an object of class X is constructed. You can use the static member b as an initializer because b is
created independently of any objects of class X. You can declare the member b after its use as a default
argument because the default values are not analyzed until after the final bracket } of the class
declaration.

class X
{
    int a;
    f(int z = a); // error
    g(int z = b); // valid
    static int b;
};

Pointers to functions

A pointer to a function points to the address of the executable code of the function. You can use pointers
to call functions and to pass functions as arguments to other functions. You cannot perform pointer
arithmetic on pointers to functions.

For z/OS XL C/C++, use the _cdecl keyword to declare a pointer to a function as a C linkage.
For more information, refer to "The _cdecl function specifier (C++ only)" on page 195.

The type of a pointer to a function is based on both the return type and parameter types of the function.

A declaration of a pointer to a function must have the pointer name in parentheses. The function call
operator () has a higher precedence than the dereference operator *. Without them, the compiler
interprets the statement as a function that returns a pointer to a specified return type. For example:

```
int *f(int a);  /* function f returning an int*/
int (*)(int a); /* pointer g to a function returning an int*/
char (*)(int, int) /* h is a function
    that takes two integer parameters and returns char*/
```

In the first declaration, f is interpreted as a function that takes an int as argument, and returns a pointer
to an int. In the second declaration, g is interpreted as a pointer to a function that takes an int argument
and that returns an int.

You can use a trailing return type in the declaration or definition of a pointer to a function. For example:
```
auto(*fp)() -> int;
```

In this example, fp is a pointer to a function that returns int. You can rewrite the declaration of fp without
using a trailing return type as int (*fp)(void). For more information on trailing return type, see "Trailing;
Under z/OS XL C/C++, if you pass a function pointer to a function, or the function returns a function pointer, the declared or implied linkages must be the same. Use the `extern` keyword with declarations in order to specify different linkages.

The following example illustrates the correct and incorrect uses of function pointers under z/OS XL C/C++:

```c
#include <stdlib.h>

extern "C" int cf();
extern "C++" int cxxf(); // C++ is included here for clarity;
// it is not required; if it is
// omitted, cxxf() will still have // C++ linkage.
extern "C" int (*c_fp)();
extern "C++" int (*cxx_fp)();
typedef int (*dft_fp_T)();
typedef int (dft_f_T)();

extern "C" {
typedef void (*cfp_T)();
typedef int (*cf_pT)();
void cfn();
void (*cfp)();
}

extern "C++" {
typedef int (*cxxf_pT)();
void cxxfn();
void (*cxxfp)();
}

extern "C" void f_cprm(int (*f)()) {
  int (*s)() = cxxf; // error, incompatible linkages-cxxf has
  // C++ linkage, s has C linkage as it
  // is included in the extern "C" wrapper
  cxxf_pT j = cxxf; // valid, both have C++ linkage
  int (*i)() = cf; // valid, both have C linkage
}

extern "C++" void f_cxprm(int (*f)()) {
  int (*s)() = cf; // error, incompatible linkages-cf has C
  // linkage, s has C++ linkage as it is
  // included in the extern "C++" wrapper
  int (*i)() = cxxf; // valid, both have C++ linkage
  cf_pT j = cf; // valid, both have C linkage
}

main() {
  c_fp = cxxf; // error - c_fp has C linkage and cxxf has
  // C++ linkage
  cxx_fp = cf; // error - cxx_fp has C++ linkage and
  // cf has C linkage
  dft_fp_T dftfpT1 = cf; // error - dftfpT1 has C++ linkage and
  // cf has C linkage
  dft_f_T *dftfT3 = cf; // error - dftfT3 has C++ linkage and
  // cf has C linkage
  dft_fp_T dftfpT5 = cxxf; // valid
  dft_f_T *dftfT6 = cxxf; // valid
```
c_fp = cf;     // valid
cxx_fp = cxxf; // valid
f_cprm(cf);   // valid
f_cxprm(cxxf); // valid

// The following errors are due to incompatible linkage of function arguments, type conversion not possible
f_cprm(cxxf); // error - f_cprm expects a parameter with C linkage, but cxxf has C++ linkage
f_cxprm(cf); // error - f_cxprm expects a parameter with C++ linkage, but cf has C linkage

For z/OS, linkage compatibility affects all C library functions that accept a function pointer as a parameter.

References to functions

A reference to a function is an alias or an alternative name for a function. You must initialize all references to functions after they are defined. Once defined, a reference to a function cannot be reassigned. You can use references to call functions and to pass functions as arguments to other functions. For example:

```c
int g();

// f is a reference to a function that has no parameters and returns int.
int bar(int(&f)()){
    // call function f that is passed as an argument.
    return f();
}
int x = bar(g);
```

You can also use a trailing return type in the declaration or definition of a reference to a function. In the following example, `fp` is a reference to a function that returns `int`. For more information on trailing return type, see "Trailing return type (C++0x)" on page 202.

```c
auto(&fp)()->int;
```

Chapter 9. Namespaces (C++ only)

A namespace is an optionally named scope. You declare names inside a namespace as you would for a class or an enumeration. You can access names declared inside a namespace the same way you access a nested class name by using the scope resolution (::) operator. However namespaces do not have the additional features of classes or enumerations. The primary purpose of the namespace is to add an additional identifier (the name of the namespace) to a name.

Defining namespaces

In order to uniquely identify a namespace, use the namespace keyword.

Namespace syntax

```
inline namespace identifier {
  namespace_body
}
```

The identifier in an original namespace definition is the name of the namespace. The identifier may not be previously defined in the declarative region in which the original namespace definition appears, except in the case of extending namespace. If an identifier is not used, the namespace is an unnamed namespace.

Related reference

"Unnamed namespaces" on page 223
"Inline namespace definitions (C++0x)" on page 227

Declaring namespaces

The identifier used for a namespace name should be unique. It should not be used previously as a global identifier.

```
namespace Raymond {
  // namespace body here...
}
```

In this example, Raymond is the identifier of the namespace. If you intend to access a namespace's elements, the namespace's identifier must be known in all translation units.

Related reference

"File/global scope" on page 3

Creating a namespace alias

An alternate name can be used in order to refer to a specific namespace identifier.

```
namespace INTERNATIONAL_BUSINESS_MACHINES {
  void f();
}
```

namespace IBM = INTERNATIONAL_BUSINESS_MACHINES;

In this example, the IBM identifier is an alias for INTERNATIONAL_BUSINESS_MACHINES. This is useful for referring to long namespace identifiers.

If a namespace name or alias is declared as the name of any other entity in the same declarative region, a compile-time error will result. Also, if a namespace name defined at global scope is declared as the name of any other entity in any global scope of the program, a compile-time error will result.
Creating an alias for a nested namespace

Namespace definitions hold declarations. Since a namespace definition is a declaration itself, namespace definitions can be nested.

An alias can also be applied to a nested namespace.

```cpp
namespace INTERNATIONAL_BUSINESS_MACHINES {
    int j;
    namespace NESTED IBM_PRODUCT {
        void a() { j++; }
        int j;
        void b() { j++; }
    }
}
namespace NIBM = INTERNATIONAL BUSINESS MACHINES::NESTED IBM PRODUCT
```

In this example, the NIBM identifier is an alias for the namespace NESTED IBM PRODUCT. This namespace is nested within the INTERNATIONAL BUSINESS MACHINES namespace.

Extending namespaces

Namespaces are extensible. You can add subsequent declarations to a previously defined namespace. Extensions may appear in files separate from or attached to the original namespace definition. For example:

```cpp
namespace X { // namespace definition
    int a;
    int b;
}
namespace X { // namespace extension
    int c;
    int d;
}
namespace Y { // equivalent to namespace X
    int a;
    int b;
    int c;
    int d;
}
```

In this example, namespace X is defined with a and b and later extended with c and d. namespace X now contains all four members. You may also declare all of the required members within one namespace. This method is represented by namespace Y. This namespace contains a, b, c, and d.

Namespaces and overloading

You can overload functions across namespaces. For example:

```cpp
// Original X.h:
f(int);
// Original Y.h:
```
f(char);

// Original program.c:
#include "X.h"
#include "Y.h"

void z()
{
    f('a'); // calls f(char) from Y.h
}

Namespaces can be introduced to the previous example without drastically changing the source code.

// New X.h:
namespace X {
    f(int);
}

// New Y.h:
namespace Y {
    f(char);
}

// New program.c:
#include "X.h"
#include "Y.h"

using namespace X;
using namespace Y;

void z()
{
    f('a'); // calls f() from Y.h
}

In program.c, function void z() calls function f(), which is a member of namespace Y. If you place the using directives in the header files, the source code for program.c remains unchanged.

Unnamed namespaces

A namespace with no identifier before an opening brace produces an unnamed namespace. Each translation unit may contain its own unique unnamed namespace. The following example demonstrates how unnamed namespaces are useful.

#include <iostream>

using namespace std;

namespace {
    const int i = 4;
    int variable;
}

int main()
{
    cout << i << endl;
    variable = 100;
    return 0;
}

In the previous example, the unnamed namespace permits access to i and variable without using a scope resolution operator.
The following example illustrates an improper use of unnamed namespaces.

```cpp
#include <iostream>

using namespace std;

namespace {
    const int i = 4;
}

int i = 2;

int main()
{
    cout << i << endl; // error
    return 0;
}
```

Inside `main`, `i` causes an error because the compiler cannot distinguish between the global name and the unnamed namespace member with the same name. In order for the previous example to work, the namespace must be uniquely identified with an identifier and `i` must specify the namespace it is using.

You can extend an unnamed namespace within the same translation unit. For example:

```cpp
#include <iostream>

using namespace std;

namespace {
    int variable;
    void funct (int);
}

namespace {
    void funct (int i) { cout << i << endl; }
}

int main()
{
    funct(variable);
    return 0;
}
```

both the prototype and definition for `funct` are members of the same unnamed namespace.

Note: Items defined in an unnamed namespace have internal linkage. Rather than using the keyword `static` to define items with internal linkage, define them in an unnamed namespace instead.

Related reference
* "Program linkage" on page 6
* "Internal linkage" on page 7

Namespace member definitions

A namespace can define its own members within itself or externally using explicit qualification. The following is an example of a namespace defining a member internally:

```cpp
namespace A {
    void b() { /* definition */ }
}
```

Within namespace `A` member `void b()` is defined internally.
A namespace can also define its members externally using explicit qualification on the name being defined. The entity being defined must already be declared in the namespace and the definition must appear after the point of declaration in a namespace that encloses the declaration's namespace.

The following is an example of a namespace defining a member externally:

```cpp
namespace A {
    namespace B {
        void f();
    }
    void B::f() { /* defined outside of B */ }
}
```

In this example, function `f()` is declared within namespace `B` and defined (outside `B`) in `A`.

### Namespaces and friends

Every name first declared in a namespace is a member of that namespace. If a `friend` declaration in a non-local class first declares a class or function, the friend class or function is a member of the innermost enclosing namespace.

The following is an example of this structure:

```cpp
// f has not yet been defined
void z(int);
namespace A {
    class X {
        friend void f(X); // A::f is a friend
    };
    // A::f is not visible here
    X x;
    void f(X) { /* definition */} // f() is defined and known to be a friend
}
```

```cpp
using A::x;
```

```cpp
void z()
{
    A::f(x); // OK
    A::X::f(x); // error: f is not a member of A::X
}
```

In this example, function `f()` can only be called through namespace `A` using the call `A::f(s)`; Attempting to call function `f()` through class `X` using the `A::X::f(x)` call results in a compile-time error. Since the friend declaration first occurs in a non-local class, the friend function is a member of the innermost enclosing namespace and may only be accessed through that namespace.

**Related reference**

“Friends” on page 270

### The using directive

A using directive provides access to all namespace qualifiers and the scope operator. This is accomplished by applying the using keyword to a namespace identifier.

**Using directive syntax**

```
using namespace name;
```
The name must be a previously defined namespace. The using directive may be applied at the global and local scope but not the class scope. Local scope takes precedence over global scope by hiding similar declarations with some exceptions.

For unqualified name lookup, if a scope contains a using directive that nominates a second namespace and that second namespace contains another using directive, the using directive from the second namespace acts as if it resides within the first scope.

```c++
namespace A {
    int i;
}
namespace B {
    int i;
    using namespace A;
}
void f()
{
    using namespace B;
    i = 7; // error
}
```

In this example, attempting to initialize `i` within function `f()` causes a compile-time error, because function `f()` does not know which `i` to call; `i` from namespace `A`, or `i` from namespace `B`.

- "Inline namespace definitions (C++0x)" on page 227

### The using declaration and namespaces

A using declaration provides access to a specific namespace member. This is accomplished by applying the using keyword to a namespace name with its corresponding namespace member.

**using declaration syntax**

```
using namespace ::member
```

In this syntax diagram, the qualifier name follows the using declaration and the member follows the qualifier name. For the declaration to work, the member must be declared inside the given namespace. For example:

```c++
namespace A {
    int i;
    int k;
    void f;
    void g;
}
using A::k
```

In this example, the using declaration is followed by `A`, the name of namespace `A`, which is then followed by the scope operator (::), and `k`. This format allows `k` to be accessed outside of namespace `A` through a using declaration. After issuing a using declaration, any extension made to that specific namespace will not be known at the point at which the using declaration occurs.

Overloaded versions of a given function must be included in the namespace prior to that given function's declaration. A using declaration may appear at namespace, block and class scope.
Explicit access

To explicitly qualify a member of a namespace, use the namespace identifier with a :: scope resolution operator.

Explicit access qualification syntax

```
namespace_name::member
```

For example:

```cpp
namespace VENDITTI {
    void j();
}
VENDITTI::j();
```

In this example, the scope resolution operator provides access to the function j held within namespace VENDITTI. The scope resolution operator :: is used to access identifiers in both global and local namespaces. Any identifier in an application can be accessed with sufficient qualification. Explicit access cannot be applied to an unnamed namespace.

Inline namespace definitions (C++0x)

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

Inline namespace definitions are namespace definitions with an initial `inline` keyword. A namespace so defined is an inline namespace. You can define and specialize members of an inline namespace as if they were also members of the enclosing namespace.

Inline namespace definitions syntax

```
inline namespace_definition
```

When an inline namespace is defined, a `using` directive is implicitly inserted into its enclosing namespace. While looking up a qualified name through the enclosing namespace, members of the inline namespace are brought in and found by the implicit `using` directive, even if that name is declared in the enclosing namespace.

For example, if you compile the following code with USE_INLINE_B defined, the output of the resulting executable is 1; otherwise, the output is 2.

```cpp
namespace A {
    #if USE_INLINE_B
        inline
        #endif
    namespace B {
        int foo(bool) { return 1; }
    }
}
```
The properties of inline namespace definitions are transitive; that is, you can use members of an inline namespace as if they were also members of any namespace in its enclosing namespace set, which consists of the innermost non-inline namespace enclosing the inline namespace, together with any intervening inline namespaces. For example:

```cpp
namespace L {
    inline namespace M {
        inline namespace N {
            /*...*/
        }
    }
}
```

In this example, a namespace L contains an inline namespace M, which in turn contains another inline namespace N. The members of N can also be used as if they were members of the namespaces in its enclosing namespace set, i.e., L and M.

Notes:
- Do not declare the namespace std, which is used for the C++ standard library, as an inline namespace.
- Do not declare a namespace to be an inline namespace if it is not inline in its first definition.
- You can declare an unnamed namespace as an inline namespace.

Using inline namespace definitions in explicit instantiation and specialization

You can explicitly instantiate or specialize each member of an inline namespace as if it were a member of its enclosing namespace. Name lookup for the primary template of an explicit instantiation or specialization in a namespace, for example M, considers the inline namespaces whose enclosing namespace set includes M. For example:

```cpp
namespace L {
    inline namespace M {
        template <typename T> class C;
    }

    template <typename T> void f(T) { /*...*/ }; //template specialization
}
```

```cpp
struct X { /*...*/ };
namespace L {
    template<> class C<X> { /*...*/ }; //template specialization
}
```

```cpp
int main()
{
    L::C<X> r;
    f(r); // fine, L is an associated namespace of C
}
```

In this example, M is an inline namespace of its enclosing namespace L, class C is a member of inline namespace M, so L is an associated namespace of class C.

The following rules apply when you use inline namespace definitions in explicit instantiation and specialization:
An explicit instantiation must be in an enclosing namespace of the primary template if the template name is qualified; otherwise, it must be in the nearest enclosing namespace of the primary template or a namespace in the enclosing namespace set.

An explicit specialization declaration must first be declared in the namespace scope of the nearest enclosing namespace of the primary template, or a namespace in the enclosing namespace set. If the declaration is not a definition, it may be defined later in any enclosing namespace.

Using inline namespace definitions in library versioning

With inline namespace definitions, you can provide a common source interface for a library with several implementations, and a user of the library can choose one implementation to be associated with the common interface. The following example demonstrates the use of inline namespace in library versioning with explicit specialization.

```cpp
//foo.h
#ifndef SOME_LIBRARY_FOO_H_
#define SOME_LIBRARY_FOO_H_
namespace SomeLibrary {
    #ifdef SOME_LIBRARY_USE_VERSION_2_
    inline namespace version_2 { }
    #else
    inline namespace version_1 { }
    #endif
    namespace version_1 {
        template <typename T> int foo(T a) {return 1;}
    }
    namespace version_2 {
        template <typename T> int foo(T a) {return 2;}
    }
}
#endif

//myFooCaller.C
#include <Foo.h>
#include <iostream>
struct MyIntWrapper { int x;};
namespace SomeLibrary {
    template <> int foo(MyIntWrapper a) { return a.x;}
}

int main(void) {
    using namespace SomeLibrary;
    MyIntWrapper intWrap = { 4 };
    std::cout << foo(intWrap) + foo(1.0) << std::endl;
}
```

If you compile this example with SOME_LIBRARY_USE_VERSION_2_ defined, the output of the resulting executable is 6; otherwise, the output is 5. If the function call, `foo(intWrap)`, is qualified with one of the inline namespaces, then you need to ensure that the explicit specialization is effective.
Chapter 10. Overloading (C++ only)

If you specify more than one definition for a function name or an operator in the same scope, you have overloaded that function name or operator. Overloaded functions and operators are described in “Overloading functions” and “Overloading operators” on page 233, respectively.

An overloaded declaration is a declaration that had been declared with the same name as a previously declared declaration in the same scope, except that both declarations have different types.

If you call an overloaded function name or operator, the compiler determines the most appropriate definition to use by comparing the argument types you used to call the function or operator with the parameter types specified in the definitions. The process of selecting the most appropriate overloaded function or operator is called overload resolution, as described in “Overload resolution” on page 241.

Overloading functions

You overload a function name \( f \) by declaring more than one function with the name \( f \) in the same scope. The declarations of \( f \) must differ from each other by the types and/or the number of arguments in the argument list. When you call an overloaded function named \( f \), the correct function is selected by comparing the argument list of the function call with the parameter list of each of the overloaded candidate functions with the name \( f \). A candidate function is a function that can be called based on the context of the call of the overloaded function name.

Consider a function \( \text{print} \), which displays an \( \text{int} \). As shown in the following example, you can overload the function \( \text{print} \) to display other types, for example, \( \text{double} \) and \( \text{char*} \). You can have three functions with the same name, each performing a similar operation on a different data type:

```cpp
#include <iostream>
using namespace std;

void print(int i) {
    cout << "Here is int " << i << endl;
}

void print(double f) {
    cout << "Here is float " << f << endl;
}

void print(char* c) {
    cout << "Here is char* " << c << endl;
}

int main() {
    print(10);
    print(10.10);
    print("ten");
}
```

The following is the output of the above example:

```
Here is int 10
Here is float 10.1
Here is char* ten
```
Restrictions on overloaded functions

You cannot overload the following function declarations even if they appear in the same scope. Note that this list applies only to explicitly declared functions and those that have been introduced through using declarations:

- Function declarations that differ only by return type. For example, you cannot use the following declarations:

```cpp
int f();
float f();
```

- Member function declarations that have the same name and the same parameter types, but one of these declarations is a static member function declaration. For example, you cannot use the following two member function declarations of `f()`:

```cpp
struct A {
    static int f();
    int f();
};
```

- Member function template declarations that have the same name, the same parameter types, and the same template parameter lists, but one of these declarations is a static template member function declaration.

- Function declarations that have equivalent parameter declarations. These declarations are not allowed because they would be declaring the same function.

- Function declarations with parameters that differ only by the use of `typedef` names that represent the same type. Note that a `typedef` is a synonym for another type, not a separate type. For example, the following two declarations of `f()` are declarations of the same function:

```cpp
typedef int I;
void f(float, int);
void f(float, I);
```

- Function declarations with parameters that differ only because one is a pointer and the other is an array. For example, the following are declarations of the same function:

```cpp
f(char*);
f(char[10]);
```

The first array dimension is insignificant when differentiating parameters; all other array dimensions are significant. For example, the following are declarations of the same function:

```cpp
g(char[10][20]);
g(char[5][20]);
```

The following two declarations are not equivalent:

```cpp
g(char[*][20]);
g(char[*][40]);
```

- Function declarations with parameters that differ only because one is a function type and the other is a pointer to a function of the same type. For example, the following are declarations of the same function:

```cpp
void f(int(float));
void f(int (*)(float));
```

- Function declarations with parameters that differ only because of cv-qualifiers `const`, `volatile`, and `restrict`. This restriction only applies if any of these qualifiers appears at the outermost level of a parameter type specification. For example, the following are declarations of the same function:

```cpp
int f(int);
int f(const int);
int f(volatile int);
```
Note that you can differentiate parameters with `const`, `volatile` and `restrict` qualifiers if you apply them within a parameter type specification. For example, the following declarations are not equivalent because `const` and `volatile` qualify `int`, rather than `*`, and thus are not at the outermost level of the parameter type specification.

```cpp
void g(int*);
void g(const int*);
void g(volatile int*);
```

The following declarations are also not equivalent:

```cpp
void g(float&);
void g(const float&);
void g(volatile float&);
```

- Function declarations with parameters that differ only because their default arguments differ. For example, the following are declarations of the same function:

```cpp
void f(int);
void f(int i = 10);
```

- Multiple functions with `extern "C"` language-linkage and the same name, regardless of whether their parameter lists are different.

### Overloading operators

You can redefine or overload the function of most built-in operators in C++. These operators can be overloaded globally or on a class-by-class basis. Overloaded operators are implemented as functions and can be member functions or global functions.

An overloaded operator is called an operator function. You declare an operator function with the keyword `operator` preceding the operator. Overloaded operators are distinct from overloaded functions, but like overloaded functions, they are distinguished by the number and types of operands used with the operator.

Consider the standard `+` (plus) operator. When this operator is used with operands of different standard types, the operators have slightly different meanings. For example, the addition of two integers is not implemented in the same way as the addition of two floating-point numbers. C++ allows you to define your own meanings for the standard C++ operators when they are applied to class types. In the following example, a class called `complx` is defined to model complex numbers, and the `+` (plus) operator is redefined in this class to add two complex numbers.

```cpp
// This example illustrates overloading the plus (+) operator.

#include <iostream>
using namespace std;

class complx
{
    double real,
            imag;
public:
    complx( double real = 0., double imag = 0.); // constructor
    complx operator+(const complx&) const;     // operator+
    
};
```
// define constructor
complx::complx( double r, double i )
{
    real = r; imag = i;
}

// define overloaded + (plus) operator
complx complx::operator+ (const complx& c) const
{
    complx result;
    result.real = (this->real + c.real);
    result.imag = (this->imag + c.imag);
    return result;
}

int main()
{
    complx x(4,4);
    complx y(6,6);
    complx z = x + y; // calls complx::operator+
}

You can overload any of the following operators:

+    -    *    /    %    ^    &    |    ~
!    ==    <   >   +=   -=   *=   /=   %=
^=   &=   <=   >=   <<=  >>=  ==   !=
<=   >=   &&   ||   ++    --    ,    ->    ->
()    []    new    delete    new[]    delete[]

where () is the function call operator and [] is the subscript operator.

You can overload both the unary and binary forms of the following operators:

+    -    *

You cannot overload the following operators:

.    .*    ::    ?:

You cannot overload the preprocessor symbols # and ##.

An operator function can be either a nonstatic member function, or a nonmember function with at least one parameter that has class, reference to class, enumeration, or reference to enumeration type.

You cannot change the precedence, grouping, or the number of operands of an operator.

An overloaded operator (except for the function call operator) cannot have default arguments or an ellipsis in the argument list.

You must declare the overloaded =, [], (), and -> operators as nonstatic member functions to ensure that they receive lvalues as their first operands.

The operators new, delete, new[], and delete[] do not follow the general rules described in this section.

All operators except the = operator are inherited.
Overloading unary operators

You overload a unary operator with either a nonstatic member function that has no parameters, or a nonmember function that has one parameter. Suppose a unary operator @ is called with the statement @t, where t is an object of type T. A nonstatic member function that overloads this operator would have the following form:

\[
\text{return_type operator}@() \]

A nonmember function that overloads the same operator would have the following form:

\[
\text{return_type operator}@(T) \]

An overloaded unary operator may return any type.

The following example overloads the ! operator:

\[
\text{#include <iostream>}
\text{using namespace std;}
\text{struct X {} ;}
\text{void operator!(X) {}
\text{ \ cout \ll \ "void operator!(X)" \ll \ endl;}
\text{}}
\text{struct Y {
\text{ \ void operator!() {}
\text{ \ \ cout \ll \ "void Y::operator!()" \ll \ endl;}
\text{ \ }}
\text{}}
\text{struct Z {} ;}
\text{int main() {
\text{ \ X ox; Y oy; Z oz;}
\text{ \ !ox;}
\text{ \ !oy;}
\text{ \ // !oz;}
\text{}}
\text{}}
\text{The \ following \ \ is \ \ the \ \ output \ \ of \ \ the \ \ above \ \ example:}
\text{void operator!(X)}
\text{void Y::operator!()}
\text{The \ operator \ function \ call \ !ox \ is \ interpreted \ as \ operator!(X). \ The \ call \ !oy \ is \ interpreted \ as \ Y::operator!(). (The \ compiler \ would \ not \ allow \ !oz \ because \ the \ ! \ operator \ has \ not \ been \ defined \ for \ class \ Z.)}

Related reference

"Unary expressions" on page 123

Overloading increment and decrement operators

You overload the prefix increment operator ++ with either a nonmember function operator that has one argument of class type or a reference to class type, or with a member function operator that has no arguments.

In the following example, the increment operator is overloaded in both ways:

\[
\text{class X {
\text{ public:}
\text{}}}
\]
// member prefix ++x
void operator++() { }
};

class Y { }; // non-member prefix ++y
void operator++(Y&) { }

int main() {
X x;
Y y;

// calls x.operator++()
++x;

// explicit call, like ++x
x.operator++();

// calls operator++(y)
++y;

// explicit call, like ++y
operator++(y);
}

The postfix increment operator ++ can be overloaded for a class type by declaring a nonmember function operator operator++() with two arguments, the first having class type and the second having type int. Alternatively, you can declare a member function operator operator++() with one argument having type int. The compiler uses the int argument to distinguish between the prefix and postfix increment operators. For implicit calls, the default value is zero.

For example:
class X {
public:

    // member postfix x++
    void operator++(int) { }
};

class Y { }; // nonmember postfix y++
void operator++(Y&, int) { }

int main() {
X x;
Y y;

    // calls x.operator++(0)
    // default argument of zero is supplied by compiler
    ++x;
    // explicit call to member postfix x++
    x.operator++(0);

    // calls operator++(y, 0)
    y++;
    // explicit call to non-member postfix y++
    operator++(y, 0);
}

The prefix and postfix decrement operators follow the same rules as their increment counterparts.
Overloading binary operators

You overload a binary operator with either a nonstatic member function that has one parameter, or a nonmember function that has two parameters. Suppose a binary operator @ is called with the statement t @ u, where t is an object of type T, and u is an object of type U. A nonstatic member function that overloads this operator would have the following form:

\[
\text{return\_type\ operator\_@}(T)
\]

A nonmember function that overloads the same operator would have the following form:

\[
\text{return\_type\ operator\_@}(T, U)
\]

An overloaded binary operator may return any type.

The following example overloads the * operator:

```c++
struct X {
    // member binary operator
    void operator*(int) {};

    // non-member binary operator
    void operator*(X, float) {};

    int main() {
        X x;
        int y = 10;
        float z = 10;

        x * y;
        x * z;
    }
}
```

The call x * y is interpreted as x.operator*(y). The call x * z is interpreted as operator*(x, z).

Overloading assignments

You overload the assignment operator, operator=, with a nonstatic member function that has only one parameter. You cannot declare an overloaded assignment operator that is a nonmember function. The following example shows how you can overload the assignment operator for a particular class:

```c++
struct X {
    int data;
    X& operator=(X& a) { return a; }
    X& operator=(int a) {
        data = a;
        return *this;
    }
};

int main() {
    
```
The assignment \( x_1 = x_2 \) calls the copy assignment operator \( X& X::operator=(X&) \). The assignment \( x_1 = 5 \) calls the copy assignment operator \( X& X::operator=(\text{int}) \). The compiler implicitly declares a copy assignment operator for a class if you do not define one yourself. Consequently, the copy assignment operator (\( \text{operator=} \)) of a derived class hides the copy assignment operator of its base class.

However, you can declare any copy assignment operator as virtual. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {
    A& operator=(char) {
        cout << "A& A::operator=(char)" << endl;
        return *this;
    }
    virtual A& operator=(const A&) {
        cout << "A& A::operator=(const A&)" << endl;
        return *this;
    }
};

struct B : A {
    B& operator=(char) {
        cout << "B& B::operator=(char)" << endl;
        return *this;
    }
    virtual B& operator=(const A&) {
        cout << "B& B::operator=(const A&)" << endl;
        return *this;
    }
};

struct C : B {}

int main() {
    B b1;
    B b2;
    A* ap1 = &b1;
    A* ap2 = &b1;
    *ap1 = 'z';
    *ap2 = b2;
    // c1 = 'z';
}
```

The following is the output of the above example:

A& A::operator=(char)  
B& B::operator=(const A&)

The assignment \( *\text{ap1} = 'z' \) calls \( A& A::operator=(\text{char}) \). Because this operator has not been declared \( \text{virtual} \), the compiler chooses the function based on the type of the pointer \( \text{ap1} \). The assignment \( *\text{ap2} = \text{b2} \) calls \( B& B::operator=(\text{const A&}) \). Because this operator has been declared \( \text{virtual} \), the compiler chooses the function based on the type of the object that the pointer \( \text{ap1} \) points to. The compiler would not allow the assignment \( c1 = 'z' \) because the implicitly declared copy assignment operator declared in class \( C \) hides \( B& B::operator=(\text{char}) \).
Overloading function calls

The function call operator, when overloaded, does not modify how functions are called. Rather, it modifies how the operator is to be interpreted when applied to objects of a given type.

You overload the function call operator, `operator()`, with a nonstatic member function that has any number of parameters. If you overload a function call operator for a class its declaration will have the following form:

```
return_type operator()(parameter_list)
```

Unlike all other overloaded operators, you can provide default arguments and ellipses in the argument list for the function call operator.

The following example demonstrates how the compiler interprets function call operators:

```cpp
struct A {
    void operator()(int a, char b, ...) { }
    void operator()(char c, int d = 20) { }
};

int main() {
    A a;
    a(5, 'z', 'a', 0);
    a('z');
    // a();
}
```

The function call `a(5, 'z', 'a', 0)` is interpreted as `a.operator()(5, 'z', 'a', 0)`. This calls `void A::operator()(int a, char b, ...)`. The function call `a('z')` is interpreted as `a.operator()('z')`. This calls `void A::operator()(char c, int d = 20)`. The compiler would not allow the function call `a()` because its argument list does not match any function call parameter list defined in class `A`.

The following example demonstrates an overloaded function call operator:

```cpp
class Point {
private:
    int x, y;
public:
    Point() : x(0), y(0) { }
    Point& operator()(int dx, int dy) {
        x += dx;
        y += dy;
        return *this;
    }
};

int main() {
    Point pt;
    // Offset this coordinate x with 3 points
    // and coordinate y with 2 points.
    pt(3, 2);
}
```

The above example reinterprets the function call operator for objects of class `Point`. If you treat an object of `Point` like a function and pass it two integer arguments, the function call operator will add the values of the arguments you passed to `Point::x` and `Point::y` respectively.
Overloading subscripting

You overload `operator[]` with a nonstatic member function that has only one parameter. The following example is a simple array class that has an overloaded subscripting operator. The overloaded subscripting operator throws an exception if you try to access the array outside of its specified bounds:

```cpp
#include <iostream>
using namespace std;

template <class T> class MyArray {
private:
  T* storage;
  int size;
public:
  MyArray(int arg = 10) {
    storage = new T[arg];
    size = arg;
  }

  ~MyArray() {
    delete[] storage;
    storage = 0;
  }

  T& operator[](const int location) throw (const char*);
};

template <class T> T& MyArray<T>::operator[](const int location) throw (const char*) {
  if (location < 0 || location >= size) throw "Invalid array access";
  else return storage[location];
}

int main() {
  try {
    MyArray<int> x(13);
    x[0] = 45;
    x[1] = 2435;
    cout << x[0] << endl;
    cout << x[1] << endl;
    x[13] = 84;
  } catch (const char* e) {
    cout << e << endl;
  }
}
```

The following is the output of the above example:

```
45
2435
Invalid array access
```

The expression `x[1]` is interpreted as `x.operator[](1)` and calls `int& MyArray<int>::operator[](const int)`.

Overloading class member access

You overload `operator->` with a nonstatic member function that has no parameters. The following example demonstrates how the compiler interprets overloaded class member access operators:
struct Y {
    void f() { }
};

struct X {
    Y* ptr;
    Y* operator->() {
        return ptr;
    }
};

int main() {
    X x;
    x->f();
}

The statement x->f() is interpreted as (x.operator->())->f().

The operator-> is used (often in conjunction with the pointer-dereference operator) to implement "smart pointers." These pointers are objects that behave like normal pointers except they perform other tasks when you access an object through them, such as automatic object deletion (either when the pointer is destroyed, or the pointer is used to point to another object), or reference counting (counting the number of smart pointers that point to the same object, then automatically deleting the object when that count reaches zero).

One example of a smart pointer is included in the C++ Standard Library called auto_ptr. You can find it in the <memory> header. The auto_ptr class implements automatic object deletion.

"Arrow operator ->" on page 123

Overload resolution

The process of selecting the most appropriate overloaded function or operator is called overload resolution.

Suppose that f is an overloaded function name. When you call the overloaded function f(), the compiler creates a set of candidate functions. This set of functions includes all of the functions named f that can be accessed from the point where you called f(). The compiler may include as a candidate function an alternative representation of one of those accessible functions named f to facilitate overload resolution.

After creating a set of candidate functions, the compiler creates a set of viable functions. This set of functions is a subset of the candidate functions. The number of parameters of each viable function agrees with the number of arguments you used to call f().

The compiler chooses the best viable function, the function declaration that the C++ runtime environment will use when you call f(), from the set of viable functions. The compiler does this by implicit conversion sequences. An implicit conversion sequence is the sequence of conversions required to convert an argument in a function call to the type of the corresponding parameter in a function declaration. The implicit conversion sequences are ranked; some implicit conversion sequences are better than others. The best viable function is the one whose parameters all have either better or equal-ranked implicit conversion sequences than all of the other viable functions. The compiler will not allow a program in which the compiler was able to find more than one best viable function. Implicit conversion sequences are described in more detail in "Implicit conversion sequences" on page 242.

When a variable length array is a function parameter, the leftmost array dimension does not distinguish functions among candidate functions. In the following, the second definition of f is not allowed because void f(int []) has already been defined.
void f(int a[ ]) {}  
void f(int a[5]) {} // illegal

However, array dimensions other than the leftmost in a variable length array do differentiate candidate functions when the variable length array is a function parameter. For example, the overload set for function f might comprise the following:
void f(int a[][5]) {}  
void f(int a[][4]) {}  
void f(int a[][g]) {} // assume g is a global int

but cannot include
void f(int a[][g2]) {} // illegal, assuming g2 is a global int

because having candidate functions with second-level array dimensions g and g2 creates ambiguity about which function f should be called: neither g nor g2 is known at compile time.

You can override an exact match by using an explicit cast. In the following example, the second call to f() matches with f(void*):
void f(int) { };  
void f(void*) { };  

int main() {
  f(0xaabb); // matches f(int);  
f((void*) 0xaabb); // matches f(void*)
}

Implicit conversion sequences

An implicit conversion sequence is the sequence of conversions required to convert an argument in a function call to the type of the corresponding parameter in a function declaration.

The compiler will try to determine an implicit conversion sequence for each argument. It will then categorize each implicit conversion sequence in one of three categories and rank them depending on the category. The compiler will not allow any program in which it cannot find an implicit conversion sequence for an argument.

The following are the three categories of conversion sequences in order from best to worst:

- **Standard conversion sequences**
- “User-defined conversion sequences” on page 243
- “Ellipsis conversion sequences” on page 243

Note: Two standard conversion sequences or two user-defined conversion sequences may have different ranks.

Standard conversion sequences

Standard conversion sequences are categorized in one of three ranks. The ranks are listed in order from best to worst:

- Exact match: This rank includes the following conversions:
  - Identity conversions
  - Lvalue-to-rvalue conversions
  - Array-to-pointer conversions
  - Qualification conversions
- Promotion: This rank includes integral and floating point promotions.
- Conversion: This rank includes the following conversions:
The compiler ranks a standard conversion sequence by its worst-ranked standard conversion. For example, if a standard conversion sequence has a floating-point conversion, then that sequence has conversion rank.

**User-defined conversion sequences**

A *user-defined conversion sequence* consists of the following:
- A standard conversion sequence
- A user-defined conversion
- A second standard conversion sequence

A user-defined conversion sequence \( A \) is better than a user-defined conversion sequence \( B \) if the both have the same user-defined conversion function or constructor, and the second standard conversion sequence of \( A \) is better than the second standard conversion sequence of \( B \).

**Ellipsis conversion sequences**

An *ellipsis conversion sequence* occurs when the compiler matches an argument in a function call with a corresponding ellipsis parameter.

**Resolving addresses of overloaded functions**

If you use an overloaded function name \( f \) without any arguments, that name can refer to a function, a pointer to a function, a pointer to member function, or a specialization of a function template. Because you did not provide any arguments, the compiler cannot perform overload resolution the same way it would for a function call or for the use of an operator. Instead, the compiler will try to choose the best viable function that matches the type of one of the following expressions, depending on where you have used \( f \):
- An object or reference you are initializing
- The left side of an assignment
- A parameter of a function or a user-defined operator
- The return value of a function, operator, or conversion
- An explicit type conversion

If the compiler chose a declaration of a nonmember function or a static member function when you used \( f \), the compiler matched the declaration with an expression of type pointer-to-function or reference-to-function. If the compiler chose a declaration of a nonstatic member function, the compiler matched that declaration with an expression of type pointer-to-member function. The following example demonstrates this:
struct X {
    int f(int) { return 0; }
    static int f(char) { return 0; }
};

int main() {
    int (X::*a)(int) = &X::f;
    // int (*b)(int) = &X::f;
}

The compiler will not allow the initialization of the function pointer b. No nonmember function or static function of type int(int) has been declared.

If f is a template function, the compiler will perform template argument deduction to determine which template function to use. If successful, it will add that function to the list of viable functions. If there is more than one function in this set, including a non-template function, the compiler will eliminate all template functions from the set and choose the non-template function. If there are only template functions in this set, the compiler will choose the most specialized template function. The following example demonstrates this:

template<class T> int f(T) { return 0; }
template<> int f(int) { return 0; }
int f(int) { return 0; }

int main() {
    int (T::*a)(int) = f;
    a(1);
}

The function call a(1) calls int f(int).

Chapter 11. Classes (C++ only)

A class is a mechanism for creating user-defined data types. It is similar to the C language structure data type. In C, a structure is composed of a set of data members. In C++, a class type is like a C structure, except that a class is composed of a set of data members and a set of operations that can be performed on the class.

In C++, a class type can be declared with the keywords union, struct, or class. A union object can hold any one of a set of named members. Structure and class objects hold a complete set of members. Each class type represents a unique set of class members including data members, member functions, and other type names. The default access for members depends on the class key:

- The members of a class declared with the keyword class are private by default. A class is inherited privately by default.
- The members of a class declared with the keyword struct are public by default. A structure is inherited publicly by default.
- The members of a union (declared with the keyword union) are public by default. A union cannot be used as a base class in derivation.

Once you create a class type, you can declare one or more objects of that class type. For example:

```cpp
class X {
   /* define class members here */
};
int main()
{
   X xobject1;  // create an object of class type X
   X xobject2;  // create another object of class type X
}
```

You may have polymorphic classes in C++. Polymorphism is the ability to use a function name that appears in different classes (related by inheritance), without knowing exactly the class the function belongs to at compile time.

C++ allows you to redefine standard operators and functions through the concept of overloading. Operator overloading facilitates data abstraction by allowing you to use classes as easily as built-in types.

Declaring class types

A class declaration creates a unique type class name.

A class specifier is a type specifier used to declare a class. Once a class specifier has been seen and its members declared, a class is considered to be defined even if the member functions of that class are not yet defined.

Class specifier syntax
The `class_name` is a unique identifier that becomes a reserved word within its scope. Once a class name is declared, it hides other declarations of the same name within the enclosing scope.

The `member_list` specifies the class members, both data and functions, of the class `class_name`. If the `member_list` of a class is empty, objects of that class have a nonzero size. You can use a `class_name` within the `member_list` of the class specifier itself as long as the size of the class is not required.

The `base_clause` specifies the base class or classes from which the class `class_name` inherits members. If the `base_clause` is not empty, the class `class_name` is called a derived class.

A `structure` is a class declared with the `class_key` `struct`. The members and base classes of a structure are public by default. A `union` is a class declared with the `class_key` `union`. The members of a union are public by default; a union holds only one data member at a time.

An aggregate class is a class that has no user-defined constructors, no private or protected non-static data members, no base classes, and no virtual functions.

**Related reference**

“Class member lists” on page 255
“Derivation” on page 278

**Using class objects**

You can use a class type to create instances or objects of that class type. For example, you can declare a class, structure, and union with class names X, Y, and Z respectively:

```cpp
class X {
    // members of class X
};

struct Y {
    // members of struct Y
};

union Z {
    // members of union Z
};
```

You can then declare objects of each of these class types. Remember that classes, structures, and unions are all types of C++ classes.

```cpp
int main() {
    X xobj; // declare a class object of class type X
    Y yobj; // declare a struct object of class type Y
    Z zobj; // declare a union object of class type Z
}
```

In C++, unlike C, you do not need to precede declarations of class objects with the keywords `union`, `struct`, and `class` unless the name of the class is hidden. For example:

```cpp
struct Y { /* ... */ };
class X { /* ... */ };
int main ()
{
    int X; // hides the class name X
}
```
When you declare more than one class object in a declaration, the declarators are treated as if declared individually. For example, if you declare two objects of class S in a single declaration:

```cpp
class S { /* ... */ };  // valid
int main() {
    S S, T;  // declare two objects of class type S
}
```

this declaration is equivalent to:

```cpp
class S { /* ... */ };  // valid
int main() {
    S S;  // keyword class is required
    class S T;  // since variable S hides class type S
}
```

but is not equivalent to:

```cpp
class S { /* ... */ };  // valid
int main() {
    S S;  // error, S class type is hidden
    S T;  // error, S class type is hidden
}
```

You can also declare references to classes, pointers to classes, and arrays of classes. For example:

```cpp
class X { /* ... */ };  // valid
struct Y { /* ... */ };  // valid
union Z { /* ... */ };  // valid
int main() {
    X xobj;
    X &xref = xobj;  // reference to class object of type X
    Y *yptr;  // pointer to struct object of type Y
    Z zarray[10];  // array of 10 union objects of type Z
}
```

You can initialize classes in external, static, and automatic definitions. The initializer contains an = (equal sign) followed by a brace-enclosed, comma-separated list of values. You do not need to initialize all members of a class.

Objects of class types that are not copy restricted can be assigned, passed as arguments to functions, and returned by functions.
Classes and structures

The C++ class is an extension of the C language structure. Because the only difference between a structure and a class is that structure members have public access by default and class members have private access by default, you can use the keywords `class` or `struct` to define equivalent classes.

For example, in the following code fragment, the class `X` is equivalent to the structure `Y`:

```cpp
class X {
    // private by default
    int a;

    public:
    // public member function
    int f() { return a = 5; };
};

struct Y {
    // public by default
    int f() { return a = 5; };

    private:
    // private data member
    int a;
};
```

If you define a structure and then declare an object of that structure using the keyword `class`, the members of the object are still public by default. In the following example, `main()` has access to the members of `obj_X` even though `obj_X` has been declared using an elaborated type specifier that uses the class key `class`:

```cpp
#include <iostream>
using namespace std;

struct X {
    int a;
    int b;
};

class X obj_X;

int main() {
    obj_X.a = 0;
    obj_X.b = 1;
    cout << "Here are a and b: " << obj_X.a << " " << obj_X.b << endl;
}
```

The following is the output of the above example:

Here are a and b: 0 1
Scope of class names

A class declaration introduces the class name into the scope where it is declared. Any class, object, function or other declaration of that name in an enclosing scope is hidden.

If a class name is declared in the same scope as a function, enumerator, or object with the same name, you must refer to that class using an elaborated type specifier.

Elaborated type specifier syntax

```
class identifier
struct :: nested_name_specifier
union
enum
typename
::
template_name
```

Nested name specifier:

```
class_name
namespace_name ::
template—nested_name_specifier
```

The following example must use an elaborated type specifier to refer to class A because this class is hidden by the definition of the function A():

```cpp
class A{};
void A(class A*){};
int main()
{
    class A* x;
    A(x);
}
```

The declaration `class A* x` is an elaborated type specifier. Declaring a class with the same name of another function, enumerator, or object as demonstrated above is not recommended.

An elaborated type specifier can also be used in the incomplete declaration of a class type to reserve the name for a class type within the current scope.

Related reference

"Incomplete class declarations"

Incomplete class declarations

An incomplete class declaration is a class declaration that does not define any class members. You cannot declare any objects of the class type or refer to the members of a class until the declaration is complete. However, an incomplete declaration allows you to make specific references to a class prior to its definition as long as the size of the class is not required.

For example, you can define a pointer to the structure first in the definition of the structure second. Structure first is declared as an incomplete class declaration prior to the definition of second, and the definition of oneptr in structure second does not require the size of first:

```cpp
struct first; // incomplete declaration of struct first
struct second // complete declaration of struct second
```
```c

struct first // complete declaration of struct first
{
    second two; // define an object of class type second
    int z;
};

However, if you declare a class with an empty member list, it is a complete class declaration. For example:

class X; // incomplete class declaration
class Z {}; // empty member list
class Y
{
public:
    X yobj; // error, cannot create an object of an
             // incomplete class type
    Z zobj; // valid
};

Related reference
“Class member lists” on page 255

Nested classes

A nested class is declared within the scope of another class. The name of a nested class is local to its enclosing class. Unless you use explicit pointers, references, or object names, declarations in a nested class can only use visible constructs, including type names, static members, and enumerators from the enclosing class and global variables.

Member functions of a nested class follow regular access rules and have no special access privileges to members of their enclosing classes. Member functions of the enclosing class have no special access to members of a nested class. The following example demonstrates this:

class A {
    int x;
    class B {
    }

    class C {

        // The compiler cannot allow the following
        // declaration because A::B is private:
        // B b;
        int y;
        void f(A* p, int i) {

            // The compiler cannot allow the following
            // statement because A::x is private:
            // p->x = 1;
        }
    }
    void g(C* p) {
```
/ The compiler cannot allow the following 
// statement because C::y is private: 
// int z = p->y;

};

int main() { }

The compiler would not allow the declaration of object b because class A::B is private. The compiler would not allow the statement p->x = i because A::x is private. The compiler would not allow the statement int z = p->y because C::y is private.

You can define member functions and static data members of a nested class in namespace scope. For example, in the following code fragment, you can access the static members x and y and member functions f() and g() of the nested class nested by using a qualified type name. Qualified type names allow you to define a typedef to represent a qualified class name. You can then use the typedef with the :: (scope resolution) operator to refer to a nested class or class member, as shown in the following example:

```cpp
class outside
{
public:
  class nested
  {
    public:
      static int x;
      static int y;
      int f();
      int g();
  }; // nested

  int outside::nested::x = 5;
  int outside::nested::f() { return 0; };
}; // outside

typedef outside::nested outnest; // define a typedef
int outnest::y = 10; // use typedef with ::
int outnest::g() { return 0; };
```

However, using a typedef to represent a nested class name hides information and may make the code harder to understand.

You cannot use a typedef name in an elaborated type specifier. To illustrate, you cannot use the following declaration in the above example:

```cpp
class outnest obj;
```

A nested class may inherit from private members of its enclosing class. The following example demonstrates this:

```cpp
class A {
private:
  class B { };
  B *z;

  class C : private B {
    private:
      B y;
      // A::B y2;
      C *x;
      // A::C *x2;
  }
};
```
The nested class A::C inherits from A::B. The compiler does not allow the declarations A::B y2 and A::C *x2 because both A::B and A::C are private.

“Class scope (C++ only)” on page 4
“Scope of class names” on page 249
“Member access” on page 268
“Static members” on page 264

Local classes

A local class is declared within a function definition. Declarations in a local class can only use type names, enumerations, static variables from the enclosing scope, as well as external variables and functions.

For example:

```cpp
int x; // global variable
void f() // function definition
{
  static int y; // static variable y can be used by
  // local class
  int x; // auto variable x cannot be used by
  // local class
  extern int g(); // extern function g can be used by
  // local class

  class local // local class
  {
    int g() { return x; } // error, local variable x
    // cannot be used by g
    int h() { return y; } // valid, static variable y
    int k() { return x; } // valid, global x
    int l() { return g(); } // valid, extern function g
  };
}

int main()
{
  local* z; // error: the class local is not visible
  // ...
}
```

Member functions of a local class have to be defined within their class definition, if they are defined at all. As a result, member functions of a local class are inline functions. Like all member functions, those defined within the scope of a local class do not need the keyword inline.

A local class cannot have static data members. In the following example, an attempt to define a static member of a local class causes an error:

```cpp
void f()
{
  class local
  {
    int f(); // error, local class has noninline
    // member function
    int g() { return 0; } // valid, inline member function
    static int a; // error, static is not allowed for
    // local class
    int b; // valid, nonstatic variable
  };
  // ...
}
```

An enclosing function has no special access to members of the local class.
Local type names

Local type names follow the same scope rules as other names. Type names defined within a class declaration have class scope and cannot be used outside their class without qualification.

If you use a class name, typedef name, or a constant name that is used in a type name, in a class declaration, you cannot redefine that name after it is used in the class declaration.

For example:
```c++
int main ()
{
    typedef double db;
    struct st
    {
        db x;
        typedef int db; // error
        db y;
    };
}
```

The following declarations are valid:
```c++
typedef float T;
class s {
    typedef int T;
    void f(const T);
};
```

Here, function f() takes an argument of type s::T. However, the following declarations, where the order of the members of s has been reversed, cause an error:
```c++
typedef float T;
class s {
    void f(const T);
    typedef int T;
};
```

In a class declaration, you cannot redefine a name that is not a class name, or a typedef name to a class name or typedef name once you have used that name in the class declaration.

"Scope" on page 1
"typedef definitions" on page 66
Chapter 12. Class members and friends (C++ only)

This section discusses the declaration of class members with respect to the information hiding mechanism and how a class can grant functions and classes access to its nonpublic members by the use of the friend mechanism. C++ expands the concept of information hiding to include the notion of having a public class interface but a private implementation. It is the mechanism for limiting direct access to the internal representation of a class type by functions in a program.

Related reference

“Inherited member access” on page 281

Class member lists

An optional member list declares subobjects called class members. Class members can be data, functions, nested types, and enumerators.

Class member list syntax

```
member_declaration
=0
constant_expression
member_definition
accessSpecifier:
```

The member list follows the class name and is placed between braces. The following applies to member lists, and members of member lists:

- A member declaration or a member definition may be a declaration or definition of a data member, member function, nested type, or enumeration. (The enumerators of a enumeration defined in a class member list are also members of the class.)
- A member list is the only place where you can declare class members.
- Friend declarations are not class members but must appear in member lists.
- The member list in a class definition declares all the members of a class; you cannot add members elsewhere.
- You cannot declare a member twice in a member list.
- You may declare a data member or member function as static but not auto, extern, or register.
- You may declare a nested class, a member class template, or a member function, and define it outside the class.
- You must define static data members outside the class.
- Nonstatic members that are class objects must be objects of previously defined classes; a class A cannot contain an object of class A, but it can contain a pointer or reference to an object of class A.
- You must specify all dimensions of a nonstatic array member.

A constant initializer (= constant_expression) may only appear in a class member of integral or enumeration type that has been declared static.

A pure specifier (= 0) indicates that a function has no definition. It is only used with member functions declared as virtual and replaces the function definition of a member function in the member list.

An access specifier is one of public, private, or protected.

A member declaration declares a class member for the class containing the declaration.
Suppose A is a name of a class. The following class members of A must have a name different from A:

- All data members
- All type members
- All enumerators of enumerated type members
- All members of all anonymous union members

### Data members

Data members include members that are declared with any of the fundamental types, as well as other types, including pointer, reference, array types, bit fields, and user-defined types. You can declare a data member the same way as a variable, except that explicit initializers are not allowed inside the class definition. However, a const static data member of integral or enumeration type may have an explicit initializer.

If an array is declared as a nonstatic class member, you must specify all of the dimensions of the array.

A class can have members that are of a class type or are pointers or references to a class type. Members that are of a class type must be of a class type that has been previously declared. An incomplete class type can be used in a member declaration as long as the size of the class is not needed. For example, a member can be declared that is a pointer to an incomplete class type.

A class X cannot have a member that is of type X, but it can contain pointers to X, references to X, and static objects of X. Member functions of X can take arguments of type X and have a return type of X. For example:

```c
class X
{
    X();
    X *xptr;
    X &xref;
    static X xcount;
    X xfunc(x);
};
```

### Member functions

*Member functions* are operators and functions that are declared as members of a class. Member functions do not include operators and functions declared with the `friend` specifier. These are called *friends* of a class. You can declare a member function as static; this is called a *static member function*. A member function that is not declared as static is called a *nonstatic member function*.

The definition of a member function is within the scope of its enclosing class. The body of a member function is analyzed after the class declaration so that members of that class can be used in the member function.
function body, even if the member function definition appears before the declaration of that member in the class member list. When the function `add()` is called in the following example, the data variables `a`, `b`, and `c` can be used in the body of `add()`.

```cpp
class x
{
  public:
    int add() // inline member function add
    {return a+b+c;};
  private:
    int a,b,c;
};
```

C++0x

You can use trailing return types for member functions, including those that have complicated return types. For more information, see “Trailing return type (C++0x)” on page 202.

C++0x

**Inline member functions**

You may either define a member function inside its class definition, or you may define it outside if you have already declared (but not defined) the member function in the class definition.

A member function that is defined inside its class member list is called an *inline member function*. Member functions containing a few lines of code are usually declared inline. In the above example, `add()` is an inline member function. If you define a member function outside of its class definition, it must appear in a namespace scope enclosing the class definition. You must also qualify the member function name using the scope resolution (::) operator.

An equivalent way to declare an inline member function is to either declare it in the class with the `inline` keyword (and define the function outside of its class) or to define it outside of the class declaration using the `inline` keyword.

In the following example, member function `Y::f()` is an inline member function:

```cpp
struct Y {
  private:
    char* a;
  public:
    char* f() { return a; }
};
```

The following example is equivalent to the previous example; `Y::f()` is an inline member function:

```cpp
struct Y {
  private:
    char* a;
  public:
    char* f();
};

inline char* Y::f() { return a; }
```

The `inline` specifier does not affect the linkage of a member or nonmember function: linkage is external by default.
Member functions of a local class must be defined within their class definition. As a result, member functions of a local class are implicitly inline functions. These inline member functions have no linkage.

**Constant and volatile member functions**

A member function declared with the `const` qualifier can be called for constant and nonconstant objects. A nonconstant member function can only be called for a nonconstant object. Similarly, a member function declared with the `volatile` qualifier can be called for volatile and nonvolatile objects. A nonvolatile member function can only be called for a nonvolatile object.

**Related reference**
“The this pointer” on page 261

**Virtual member functions**

Virtual member functions are declared with the keyword `virtual`. They allow dynamic binding of member functions. Because all virtual functions must be member functions, virtual member functions are simply called virtual functions.

If the definition of a virtual function is replaced by a pure specifier in the declaration of the function, the function is said to be declared pure. A class that has at least one pure virtual function is called an abstract class.

**Related reference**
“Virtual functions” on page 294
“Abstract classes” on page 299

**Special member functions**

*Special member functions* are used to create, destroy, initialize, convert, and copy class objects. These include the following:

- Constructors
- Destructors
- Conversion constructors
- Conversion functions
- Copy constructors

For full descriptions of these functions, see Chapter 14, “Special member functions (C++ only),” on page 303.

**Member scope**

Member functions and static members can be defined outside their class declaration if they have already been declared, but not defined, in the class member list. Nonstatic data members are defined when an object of their class is created. The declaration of a static data member is not a definition. The declaration of a member function is a definition if the body of the function is also given.

Whenever the definition of a class member appears outside of the class declaration, the member name must be qualified by the class name using the `::` (scope resolution) operator.

The following example defines a member function outside of its class declaration.

CCNX11A
```cpp
#include <iostream>
using namespace std;

struct X {
    int a, b;
    // member function declaration only
    int add();
};

// global variable
int a = 10;

// define member function outside its class declaration
int X::add() { return a + b; }

int main() {
    int answer;
    X xobject;
    xobject.a = 1;
    xobject.b = 2;
    answer = xobject.add();
    cout << xobject.a << " + " << xobject.b << " = " << answer << endl;
}
```

The output for this example is: 1 + 2 = 3

All member functions are in class scope even if they are defined outside their class declaration. In the above example, the member function `add()` returns the data member `a`, not the global variable `a`.

The name of a class member is local to its class. Unless you use one of the class access operators, . (dot), or -> (arrow), or :: (scope resolution) operator, you can only use a class member in a member function of its class and in nested classes. You can only use types, enumerations and static members in a nested class without qualification with the :: operator.

The order of search for a name in a member function body is:
1. Within the member function body itself
2. Within all the enclosing classes, including inherited members of those classes
3. Within the lexical scope of the body declaration

The search of the enclosing classes, including inherited members, is demonstrated in the following example:
```cpp
class A { /* ... */
};
class B { /* ... */
};
class C { /* ... */
};
class Z : A {
    class Y : B {
        class X : C { int f(); /* ... */
    }
    }
};
int Z::Y::X f()
{
    char j;
    return 0;
}
```

In this example, the search for the name `j` in the definition of the function `f` follows this order:
1. In the body of the function `f`
2. In `X` and in its base class `C`
3. In `Y` and in its base class `B`
4. In Z and in its base class A
5. In the lexical scope of the body of f. In this case, this is global scope.

Note that when the containing classes are being searched, only the definitions of the containing classes and their base classes are searched. The scope containing the base class definitions (global scope, in this example) is not searched.

**Pointers to members**

Pointers to members allow you to refer to nonstatic members of class objects. You cannot use a pointer to member to point to a static class member because the address of a static member is not associated with any particular object. To point to a static class member, you must use a normal pointer.

You can use pointers to member functions in the same manner as pointers to functions. You can compare pointers to member functions, assign values to them, and use them to call member functions. Note that a member function does not have the same type as a nonmember function that has the same number and type of arguments and the same return type.

Pointers to members can be declared and used as shown in the following example:

```c++
#include <iostream>
using namespace std;

class X {
public:
    int a;
    void f(int b) {
        cout << "The value of b is " << b << endl;
    }
};

int main() {
    // declare pointer to data member
    int X::*ptiptr = &X::a;
    // declare a pointer to member function
    void (X::*ptfptr) (int) = &X::f;
    // create an object of class type X
    X xobject;
    // initialize data member
    xobject.*ptiptr = 10;
    cout << "The value of a is " << xobject.*ptiptr << endl;
    // call member function
    (xobject.*ptfptr) (20);
}
```

The output for this example is:
The value of a is 10
The value of b is 20

To reduce complex syntax, you can declare a `typedef` to be a pointer to a member. A pointer to a member can be declared and used as shown in the following code fragment:

```c++
typedef int X::*my_pointer_to_member;
typedef void (X::*my_pointer_to_function) (int);

int main() {
```
my_pointer_to_member ptiptr = &X::a;
my_pointer_to_function ptfptr = &X::f;
X xobject;
xobject.*ptiptr = 10;
cout << "The value of a is " << xobject.*ptiptr << endl;
(xobject.*ptfptr)(20);
}

The pointer to member operators .* and ->* are used to bind a pointer to a member of a specific class object. Because the precedence of () (function call operator) is higher than .* and ->*, you must use parentheses to call the function pointed to by ptf.

Pointer-to-member conversion can occur when pointers to members are initialized, assigned, or compared. Note that pointer to a member is not the same as a pointer to an object or a pointer to a function.

The this pointer

The keyword this identifies a special type of pointer. Suppose that you create an object named x of class A, and class A has a nonstatic member function f(). If you call the function x.f(), the keyword this in the body of f() stores the address of x. You cannot declare the this pointer or make assignments to it.

A static member function does not have a this pointer.

The type of the this pointer for a member function of a class type X, is X* const. If the member function is declared with the const qualifier, the type of the this pointer for that member function for class X, is const X* const.

A const this pointer can be used only with const member functions. Data members of the class will be constant within that function. The function is still able to change the value, but requires a const_cast to do so:

void foo::p() const{
member = 1; // illegal
const_cast <int&> (member) = 1; // a bad practice but legal
}

A better technique would be to declare member mutable.

If the member function is declared with the volatile qualifier, the type of the this pointer for that member function for class X is volatile X* const. For example, the compiler will not allow the following:

struct A {
    int a;
    int f() const { return a++; }
};

The compiler will not allow the statement a++ in the body of function f(). In the function f(), the this pointer is of type A* const. The function f() is trying to modify part of the object to which this points.

The this pointer is passed as a hidden argument to all nonstatic member function calls and is available as a local variable within the body of all nonstatic functions.

For example, you can refer to the particular class object that a member function is called for by using the this pointer in the body of the member function. The following code example produces the output a = 5:

CCNX11C
#include <iostream>
using namespace std;
struct X {
private:
  int a;
public:
  void Set_a(int a) {
    // The 'this' pointer is used to retrieve 'xobj.a'
    // hidden by the automatic variable 'a'
    this->a = a;
  }
  void Print_a() { cout << "a=" << a << endl; }
};

int main() {
  X xobj;
  int a = 5;
  xobj.Set_a(a);
  xobj.Print_a();
}

In the member function Set_a(), the statement this->a = a uses the this pointer to retrieve xobj.a hidden by the automatic variable a.

Unless a class member name is hidden, using the class member name is equivalent to using the class member name with the this pointer and the class member access operator (->).

The example in the first column of the following table shows code that uses class members without the this pointer. The code in the second column uses the variable THIS to simulate the first column's hidden use of the this pointer:
### Code without using this pointer

```cpp
#include <string>
#include <iostream>
using namespace std;

struct X {
    private:
        int len;
        char *ptr;
    public:
        int GetLen() {
            return len;
        }
        char * GetPtr() { return ptr; }
        X& Set(char *); 
        X& Cat(char *);
        X& Copy(X&);
        void Print();
    }

    X& X::Set(char *pc) {
        len = strlen(pc);
        ptr = new char[len];
        strcpy(ptr, pc);
        return *this;
    }

    X& X::Cat(char *pc) {
        len += strlen(pc);
        strcat(ptr, pc);
        return *this;
    }

    X& X::Copy(X& x) {
        Set(x.GetPtr());
        return *this;
    }

    void X::Print() {
        cout << ptr << endl;
    }

    int main() {
        X xobj1;
        xobj1.Set("abcd")
            .Cat("efgh");
        xobj1.Print();
        X xobj2;
        xobj2.Copy(xobj1)
            .Cat("ijkl");
        xobj2.Print();
    }
```

### Equivalent code, the THIS variable simulating the hidden use of the this pointer

```cpp
#include <string>
#include <iostream>
using namespace std;

struct X {
    private:
        int len;
        char *ptr;
    public:
        int GetLen (X* const THIS) { return THIS->len; }
        char * GetPtr (X* const THIS) { return THIS->ptr; }
        X& Set(X* const, char *);
        X& Cat(X* const, char *);
        X& Copy(X* const, X&);
        void Print(X* const);
    }

    X& X::Set(X* const THIS, char *pc) {
        THIS->len = strlen(pc);
        THIS->ptr = new char[THIS->len];
        strcpy(THIS->ptr, pc);
        return *THIS;
    }

    X& X::Cat(X* const THIS, char *pc) {
        THIS->len += strlen(pc);
        strcat(THIS->ptr, pc);
        return *THIS;
    }

    X& X::Copy(X* const THIS, X& x) {
        THIS->Set(THIS, x.GetPtr(&x));
        return *THIS;
    }

    void X::Print(X* const THIS) {
        cout << THIS->ptr << endl;
    }

    int main() {
        X xobj1;
        xobj1.Set(&xobj1, "abcd")
            .Cat(&xobj1, "efgh");
        xobj1.Print(&xobj1);
        X xobj2;
        xobj2.Copy(&xobj2, xobj1)
            .Cat(&xobj2, "ijkl");
        xobj2.Print(&xobj2);
    }
```

Both examples produce the following output:

- abcd<space>efgh
- abcdefghijkl
Static members

Class members can be declared using the storage class specifier static in the class member list. Only one copy of the static member is shared by all objects of a class in a program. When you declare an object of a class having a static member, the static member is not part of the class object.

A typical use of static members is for recording data common to all objects of a class. For example, you can use a static data member as a counter to store the number of objects of a particular class type that are created. Each time a new object is created, this static data member can be incremented to keep track of the total number of objects.

You access a static member by qualifying the class name using the :: (scope resolution) operator. In the following example, you can refer to the static member f() of class type X as X::f() even if no object of type X is ever declared:

```c++
struct X {
    static int f();
};

int main() {
    X::f();
}
```

You do not have to use the class member access syntax to refer to a static member; to access a static member s of class X, you could use the expression X::s. The following example demonstrates accessing a static member:

```c++
#include <iostream>
using namespace std;

struct A {
    static void f() { cout << "In static function A::f()" << endl; }
};

int main() {
    // no object required for static member
    A::f();
    A a;
    A* ap = &a;
    a.f();
ap->f();
}
```

The three statements A::f(), a.f(), and ap->f() all call the same static member function A::f().

You can directly refer to a static member in the same scope of its class, or in the scope of a class derived from the static member's class. The following example demonstrates the latter case (directly referring to a static member in the scope of a class derived from the static member's class):
```cpp
#include <iostream>
using namespace std;

int g() {
    cout << "In function g()" << endl;
    return 0;
}

class X {
public:
    static int g() {
        cout << "In static member function X::g()" << endl;
        return 1;
    }
};

class Y: public X {
public:
    static int i;
};

int Y::i = g();

int main() {
}
```

The following is the output of the above code:

In static member function X::g()

The initialization int Y::i = g() calls X::g(), not the function g() declared in the global namespace.

**Related reference**

"The static storage class specifier" on page 45
"Scope resolution operator :: (C++ only)" on page 121
"Dot operator ." on page 122
"Arrow operator ->" on page 123

**Static data members**

The declaration of a static data member in the member list of a class is not a definition. You must define the static member outside of the class declaration, in namespace scope. For example:

```cpp
class X {
public:
    static int i;
};

int X::i = 0; // definition outside class declaration
```

Once you define a static data member, it exists even though no objects of the static data member's class exist. In the above example, no objects of class X exist even though the static data member X::i has been defined.

Static data members of a class in namespace scope have external linkage. The initializer for a static data member is in the scope of the class declaring the member.

A static data member can be of any type except for void or void qualified with const or volatile. You cannot declare a static data member as mutable.

You can only have one definition of a static member in a program. Unnamed classes, classes contained within unnamed classes, and local classes cannot have static data members.
Static data members and their initializers can access other static private and protected members of their class. The following example shows how you can initialize static members using other static members, even though these members are private:

```cpp
class C {
    static int i;
    static int j;
    static int k;
    static int l;
    static int m;
    static int n;
    static int p;
    static int q;
    static int r;
    static int s;
    static int f() { return 0; }
    int a;
public:
    C() { a = 0; }
};
CC c;
int C::i = C::f(); // initialize with static member function
int C::j = C::i; // initialize with another static data member
int C::k = c.f(); // initialize with member function from an object
int C::l = c.j; // initialize with data member from an object
int C::s = c.a; // initialize with nonstatic data member
int C::r = 1; // initialize with a constant value
class Y : private C {} y;
int C::m = Y::f(); // error
int C::n = Y::r; // error
int C::p = y.r; // error
int C::q = y.f(); // error
```

The initialization of C::m, C::n, C::p, and C::q causes errors because the values used to initialize them are private members of class Y which cannot be accessed.

If a static data member is of const integral or const enumeration type, you may specify a *constant initializer* in the static data member's declaration. This constant initializer must be an integral constant expression. Note that the constant initializer is not a definition. You still need to define the static member in an enclosing namespace. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct X {
    static const int a = 76;
};

const int X::a;

int main() {
    cout << X::a << endl;
}
```

The tokens = 76 at the end of the declaration of static data member a is a constant initializer.
Static member functions

You cannot have static and nonstatic member functions with the same names and the same number and type of arguments.

Like static data members, you may access a static member function \( f() \) of a class \( A \) without using an object of class \( A \).

A static member function does not have a `this` pointer. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct X {
    private:
        int i;
        static int si;
    public:
        void set_i(int arg) {i = arg; }
        static void set_si(int arg) { si = arg; }

        void print_i() {
            cout << "Value of i = " << i << endl;
            cout << "Again, value of i = " << this->i << endl;
        }

        static void print_si() {
            cout << "Value of si = " << si << endl;
            cout << "Again, value of si = " << this->si << endl; // error
        }
};

int X::si = 77; // Initialize static data member

int main() {
    X xobj;
    xobj.set_i(11);
    xobj.print_i();

    // static data members and functions belong to the class and can be accessed without using an object of class X
    X::print_si();
    X::set_si(22);
    X::print_si();
}
```

The following is the output of the above example:

```
Value of i = 11
Again, value of i = 11
Value of si = 77
Value of si = 22
```

The compiler does not allow the member access operation `this->si` in function `A::print_si()` because this member function has been declared as static, and therefore does not have a `this` pointer.
You can call a static member function using the this pointer of a nonstatic member function. In the following example, the nonstatic member function `printall()` calls the static member function `f()` using the this pointer:

```cpp
#include <iostream>
using namespace std;

class C {
    static void f() {
        cout << "Here is i: " << i << endl;
    }
    static int i;
    int j;
public:
    C(int firstj): j(firstj) { }
    void printall();
};

void C::printall() {
    cout << "Here is j: " << this->j << endl;
    this->f();
}

int C::i = 3;

int main() {
    C obj_C(0);
    obj_C.printall();
}
```

The following is the output of the above example:
Here is j: 0
Here is i: 3

A static member function cannot be declared with the keywords `virtual`, `const`, `volatile`, or `const volatile`.

A static member function can access only the names of static members, enumerators, and nested types of the class in which it is declared. Suppose a static member function `f()` is a member of class `X`. The static member function `f()` cannot access the nonstatic members `X` or the nonstatic members of a base class of `X`.

"The this pointer" on page 261

---

**Member access**

*Member access* determines if a class member is accessible in an expression or declaration. Suppose `x` is a member of class `A`. Class member `x` can be declared to have one of the following levels of accessibility:

- **public**: `x` can be used anywhere without the access restrictions defined by private or protected.
- **private**: `x` can be used only by the members and friends of class `A`.
- **protected**: `x` can be used only by the members and friends of class `A`, and the members and friends of classes derived from class `A`.

Members of classes declared with the keyword `class` are private by default. Members of classes declared with the keyword `struct` or `union` are public by default.
To control the access of a class member, you use one of the access specifiers public, private, or protected as a label in a class member list. The following example demonstrates these access specifiers:

```cpp
g struct A {
    friend class C;
private:
    int a;
public:
    int b;
protected:
    int c;
};

g struct B : A {
    void f() {
        // a = 1;
        b = 2;
        c = 3;
    }
};

g struct C {
    void f(A x) {
        x.a = 4;
        x.b = 5;
        x.c = 6;
    }
};

g int main() {
    A y;
    // y.a = 7;
    y.b = 8;
    // y.c = 9;
    B z;
    // z.a = 10;
    z.b = 11;
    // z.c = 12;
}
```

The following table lists the access of data members `A::a`, `A::b`, and `A::c` in various scopes of the above example.

<table>
<thead>
<tr>
<th>Scope</th>
<th>A::a</th>
<th>A::b</th>
<th>A::c</th>
</tr>
</thead>
<tbody>
<tr>
<td>function B::f()</td>
<td>No access. Member A::a is private.</td>
<td>Access. Member A::b is public.</td>
<td>Access. Class B inherits from A.</td>
</tr>
<tr>
<td>function C::f()</td>
<td>Access. Class C is a friend of A.</td>
<td>Access. Member A::b is public.</td>
<td>Access. Class C is a friend of A.</td>
</tr>
<tr>
<td>object y in main()</td>
<td>No access. Member y.a is private.</td>
<td>Access. Member y.a is public.</td>
<td>No access. Member y.c is protected.</td>
</tr>
<tr>
<td>object z in main()</td>
<td>No access. Member z.a is private.</td>
<td>Access. Member z.a is public.</td>
<td>No access. Member z.c is protected.</td>
</tr>
</tbody>
</table>

An access specifier specifies the accessibility of members that follow it until the next access specifier or until the end of the class definition. You can use any number of access specifiers in any order. If you later define a class member within its class definition, its access specification must be the same as its declaration. The following example demonstrates this:
class A {
    class B;
    public:
        class B {};
};

The compiler will not allow the definition of class B because this class has already been declared as private.

A class member has the same access control regardless whether it has been defined within its class or outside its class.

Access control applies to names. In particular, if you add access control to a typedef name, it affects only the typedef name. The following example demonstrates this:

class A {
    class B {};
    public:
        typedef B C;
};

int main() {
    A::C x;
    // A::B y;
}

The compiler will allow the declaration A::C x because the typedef name A::C is public. The compiler would not allow the declaration A::B y because A::B is private.

Note that accessibility and visibility are independent. Visibility is based on the scoping rules of C++. A class member can be visible and inaccessible at the same time.

Friends

A friend of a class X is a function or class that is not a member of X, but is granted the same access to X as the members of X. Functions declared with the friend specifier in a class member list are called friend functions of that class. Classes declared with the friend specifier in the member list of another class are called friend classes of that class.

A class Y must be defined before any member of Y can be declared a friend of another class. In the following example, the friend function print is a member of class Y and accesses the private data members a and b of class X.

```
#include <iostream>
using namespace std;

class X {
    class Y {
        public:
            void print(X& x);
    };

class X {
    class Y { 
        public:
            void print(X& x);
    };
```
int a, b;
friend void Y::print(X& x);
public:
    X() : a(1), b(2) { }
};

void Y::print(X& x) {
    cout << "a is " << x.a << endl;
    cout << "b is " << x.b << endl;
}

int main() {
    X xobj;
    Y yobj;
    yobj.print(xobj);
}

The following is the output of the above example:

a is 1
b is 2

You can declare an entire class as a friend. Suppose class F is a friend of class A. This means that every member function and static data member definition of class F has access to class A.

In the following example, the friend class F has a member function print that accesses the private data members a and b of class X and performs the same task as the friend function print in the above example. Any other members declared in class F also have access to all members of class X.

CCNX11J
#include <iostream>
using namespace std;

class X {
    int a, b;
    friend class F;
public:
    X() : a(1), b(2) { }
};

class F {
public:
    void print(X& x) {
        cout << "a is " << x.a << endl;
        cout << "b is " << x.b << endl;
    }
};

int main() {
    X xobj;
    F fobj;
    fobj.print(xobj);
}

The following is the output of the above example:

a is 1
b is 2

You cannot define a class in a friend declaration. For example, the compiler does not accept the following code:
class F;
class X {
   friend class F {};
};

However, you can define a function in a friend declaration. The class must be a non-local class. The function must have namespace scope, and the function name must be unqualified. The following example demonstrates this:
class A {
   void g();
};

void z() {
   class B {
      friend void f() { }; // error
   };
}
class C {
   friend void A::g() {} // error
   friend void h() {} // error
};

The compiler accepts the definition of h(), but not the function definition of f() or g().

You cannot declare a friend with a storage class specifier.

---

**Extended friend declarations**

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

In the C++0x standard, the *extended friend declarations* feature accepts additional forms of non-function friend declarations.

**Note:** The syntactic form of extended friend declarations overlaps with the IBM old friend declaration syntax. This section is focused on the differences between the C++0x standard and the previous ISO C++ standard.

With this feature enabled, the class-key is no longer required in the context of friend declarations. This new syntax differs from the C++98 friend class declaration syntax, where the class-key is necessary as part of an elaborated-type-specifier. See the following example:
class F;
class G;
class X1 {
   //C++98 friend declarations remain valid in C++0x.
   friend class F;
   //Error in C++98 for missing the class-key.
   friend G;
};
class X2 {
   //Error in C++98 for missing the class-key.
   //Error in C++0x for lookup failure (no previous class D declaration).

---

272 z/OS V1R13.0 XL C/C++ Language Reference
friend D;
friend class D;
};

In addition to functions and classes, you can also declare template parameters and basic types as friends. In this case, you cannot use an elaborated-type-specifier in the friend declaration. In the following example, you can declare the template parameter T as a friend of class F, and you can use the basic type char in friend declarations.

class C;

template<typename T, typename U> class F {
    //C++0x compiles successfully.
    //Error in C++98 for missing the class-key.
    friend T;

    //Error in both C++98 and C++0x: a template parameter
    //must not be used in an elaborated type specifier.
    friend class U;
};

F<C> rc;
F<char> Ri;

You can also declare typedef names as friends, but you still cannot use an elaborated-type-specifier in the friend declaration. The following example demonstrates that the typedef name D is declared as a friend of class Base.

class Derived;
typedef Derived D;

class C;
typedef C Ct;

class Base(
    public:
    Base() : x(55) {}

    //C++0x compiles sucessfully.
    //Error in C++98 for missing the class-key.
    friend D;

    //Error in both C++98 and C++0x: a typedef name
    //must not be used in an elaborated type specifier.
    friend class Ct;

    private:
    int x;
   );

struct Derived : public Base {
    int foo() { return this->x; }
};

int main() {
    Derived d;
    return d.foo();
}

This feature also introduces a new name lookup rule for friend declarations. If a friend class declaration does not use an elaborated-type-specifier, then the compiler also looks for the entity name in scopes outside the innermost namespace that encloses the friend declaration. Consider the following example:
struct T {};

namespace N {
    struct A {
        friend T;
    };
}

In this example, if this feature is in effect, the friend declaration statement does not declare a new entity T, but looks for T. If there is no T found, then the compiler issues an error. Consider another example:

struct T {};

namespace N {
    struct A {
        friend class T; //fine, no error
    };
}

In this example, the friend declaration statement does not look for T outside namespace N, nor does it find ::T. Instead, this statement declares a new class T in namespace N.

Friend scope

The name of a friend function or class first introduced in a friend declaration is not in the scope of the class granting friendship (also called the enclosing class) and is not a member of the class granting friendship.

The name of a function first introduced in a friend declaration is in the scope of the first nonclass scope that contains the enclosing class. The body of a function provided inside a friend declaration is handled in the same way as a member function defined within a class. Processing of the definition does not start until the end of the outermost enclosing class. In addition, unqualified names in the body of the function definition are searched for starting from the class containing the function definition.

A friend class name first introduced by a friend declaration is considered to belong to the first nonclass enclosing scope. Until a matching declaration is provided in that scope, the class name is not found by name lookup. For example:

namespace A { //the first nonclass scope
    class B {
        class C {
            friend class D;
        }
    };
}

In this example, the first nonclass scope that encloses the friend declaration of class D is namespace A, so friend class D is in the scope of namespace A.
If the name of a friend class has been introduced before the friend declaration, the compiler searches for a class name that matches the name of the friend class beginning at the scope of the friend declaration. If the declaration of a nested class is followed by the declaration of a friend class with the same name, the nested class is a friend of the enclosing class.

If the friend function is a member of another class, you need to use the scope resolution operator (::). For example:

```cpp
class A {
public:
    int f() { }
};

class B {
    friend int A::f();
};
```

Friends of a base class are not inherited by any classes derived from that base class. The following example demonstrates this:

```cpp
class A {
    friend class B;
    int a;
};
class B { }

class C : public B {
    void f(A* p) {
        p->a = 2; // error
    }
};
```

The compiler does not support the statement `p->a = 2` because class `C` is not a friend of class `A`, although `C` inherits from a friend of `A`.

Friendship is not transitive. The following example demonstrates this:

```cpp
class A {
    friend class B;
    int a;
};
class B { }

class C {
    friend class C;
};

class C {
    void f(A* p) {
        p->a = 2; // error
    }
};
```

The compiler does not accept the statement `p->a = 2` because class `C` is not a friend of class `A`, although `C` is a friend of a friend of `A`.

If you declare a friend in a local class, and the friend name is unqualified, the compiler looks for the name only within the innermost enclosing nonclass scope. You must declare a function before declaring it as a friend of a local scope class. You do not have to do so with classes. The following example demonstrates this:

```cpp
class X {};
void a();
void f() {
```
class Y { }
void b();
class A {
   friend class X;
   friend class Y;
   friend class Z;
   friend void a(); // error
   friend void b();
   friend void c(); // error
};
::X moocow;
X moocow2;
}

In the above example, the compiler accepts the following statements:

- **friend class X**: This statement does not declare ::X as a friend of A, but the local class X as a friend, even though this class is not otherwise declared.
- **friend class Y**: Local class Y has been declared in the scope of f().
- **friend class Z**: This statement declares the local class Z as a friend of A even though Z is not otherwise declared.
- **friend void b()**: Function b() has been declared in the scope of f().
- **::X moocow**: This declaration creates an object of the nonlocal class ::X.
- **X moocow2**: This declaration also creates an object of the nonlocal class ::X.

The compiler does not accept the following statements:

- **friend void a()**: This statement does not consider function a() declared in namespace scope. Since function a() has not been declared in the scope of f(), the compiler does not accept this statement.
- **friend void c()**: Since function c() has not been declared in the scope of f(), the compiler does not accept this statement.

- "Nested classes" on page 250
- "Local classes" on page 252

**Friend access**

A friend of a class can access the private and protected members of that class. Normally, you can only access the private members of a class through member functions of that class, and you can only access the protected members of a class through member functions of a class or classes derived from that class.

Friend declarations are not affected by access specifiers.

**Related reference**

- "Member access" on page 268
Chapter 13. Inheritance (C++ only)

_Inheritance_ is a mechanism of reusing and extending existing classes without modifying them, thus producing hierarchical relationships between them.

Inheritance is almost like embedding an object into a class. Suppose that you declare an object _x_ of class _A_ in the class definition of _B_. As a result, class _B_ will have access to all the public data members and member functions of class _A_. However, in class _B_, you have to access the data members and member functions of class _A_ through object _x_. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

class A {
   int data;
public:
   void f(int arg) { data = arg; }
   int g() { return data; }
};
class B {
public:
   A x;
};

int main() {
   B obj;
   obj.x.f(20);
   cout << obj.x.g() << endl;
   // cout << obj.g() << endl;
}
```

In the main function, object _obj_ accesses function _A::f_() through its data member _B::x_ with the statement _obj.x.f(20)_.

Object _obj_ accesses _A::g_() in a similar manner with the statement _obj.x.g_(). The compiler would not allow the statement _obj.g_() because _g_() is a member function of class _A_, not class _B_.

Inheritance lets you include the names and definitions of another class's members as part of a new class. The class whose members you want to include in your new class is called a _base class_. Your new class is _derived_ from the base class. The new class contains a _subobject_ of the type of the base class. The following example is the same as the previous example except it uses the inheritance mechanism to give class _B_ access to the members of class _A_:

```cpp
#include <iostream>
using namespace std;

class A {
   int data;
public:
   void f(int arg) { data = arg; }
   int g() { return data; }
};
class B : public A {};

int main() {
   B obj;
   obj.f(20);
   cout << obj.g() << endl;
}
```

© Copyright IBM Corp. 1998, 2011
Class A is a base class of class B. The names and definitions of the members of class A are included in the definition of class B; class B inherits the members of class A. Class B is derived from class A. Class B contains a subobject of type A.

You can also add new data members and member functions to the derived class. You can modify the implementation of existing member functions or data by overriding base class member functions or data in the newly derived class.

You may derive classes from other derived classes, thereby creating another level of inheritance. The following example demonstrates this:

```
struct A {};
struct B : A {};
struct C : B {};
```

Class B is a derived class of A, but is also a base class of C. The number of levels of inheritance is only limited by resources.

Multiple inheritance allows you to create a derived class that inherits properties from more than one base class. Because a derived class inherits members from all its base classes, ambiguities can result. For example, if two base classes have a member with the same name, the derived class cannot implicitly differentiate between the two members. Note that, when you are using multiple inheritance, the access to names of base classes may be ambiguous. See “Multiple inheritance” on page 288 for more detailed information.

A direct base class is a base class that appears directly as a base specifier in the declaration of its derived class.

An indirect base class is a base class that does not appear directly in the declaration of the derived class but is available to the derived class through one of its base classes. For a given class, all base classes that are not direct base classes are indirect base classes. The following example demonstrates direct and indirect base classes:

```
class A {
   public:
      int x;
   };
class B : public A {
   public:
      int y;
   };
class C : public B {};
```

Class B is a direct base class of C. Class A is a direct base class of B. Class A is an indirect base class of C. (Class C has x and y as its data members.)

Polymorphic functions are functions that can be applied to objects of more than one type. In C++, polymorphic functions are implemented in two ways:

- Overloaded functions are statically bound at compile time.
- C++ provides virtual functions. A virtual function is a function that can be called for a number of different user-defined types that are related through derivation. Virtual functions are bound dynamically at run time. They are described in more detail in "Virtual functions" on page 294.

## Derivation

Inheritance is implemented in C++ through the mechanism of derivation. Derivation allows you to derive a class, called a derived class, from another class, called a base class.
In the declaration of a derived class, you list the base classes of the derived class. The derived class inherits its members from these base classes.

The qualified_classSpecifier must be a class that has been previously declared in a class declaration.

An access specifier is one of public, private, or protected.

The virtual keyword can be used to declare virtual base classes.

The following example shows the declaration of the derived class D and the base classes V, B1, and B2. The class B1 is both a base class and a derived class because it is derived from class V and is a base class for D:

```cpp
class V { /* ... */ };  
class B1 : virtual public V { /* ... */ };  
class B2 { /* ... */ };  
class D : public B1, private B2 { /* ... */ };  
```

Classes that are declared but not defined are not allowed in base lists.

For example:

```cpp
class X;  
// error  
class Y: public X { };  
```

The compiler will not allow the declaration of class Y because X has not been defined.

When you derive a class, the derived class inherits class members of the base class. You can refer to inherited members (base class members) as if they were members of the derived class. For example:

```cpp
CCNX14A

class Base {  
public:  
    int a,b;  
};  

class Derived : public Base {  
public:  
    int c;  
};  

int main() {  
    Derived d;  
    d.a = 1;  // Base::a  
    d.b = 2;  // Base::b  
    d.c = 3;  // Derived::c  
}  
```
The derived class can also add new class members and redefine existing base class members. In the above example, the two inherited members, a and b, of the derived class d, in addition to the derived class member c, are assigned values. If you redefine base class members in the derived class, you can still refer to the base class members by using the :: (scope resolution) operator. For example:

```
#include <iostream>
using namespace std;

class Base {
public:
    char* name;
    void display() {
        cout << name << endl;
    }
};

class Derived: public Base {
public:
    char* name;
    void display() {
        cout << name << "\", " << Base::name << endl;
    }
};

int main() {
    Derived d;
    d.name = "Derived Class";
    d.Base::name = "Base Class";

    // call Derived::display()
    d.display();

    // call Base::display()
    d.Base::display();
}
```

The following is the output of the above example:

Derived Class, Base Class
Base Class

You can manipulate a derived class object as if it were a base class object. You can use a pointer or a reference to a derived class object in place of a pointer or reference to its base class. For example, you can pass a pointer or reference to a derived class object D to a function expecting a pointer or reference to the base class of D. You do not need to use an explicit cast to achieve this; a standard conversion is performed. You can implicitly convert a pointer to a derived class to point to an accessible unambiguous base class. You can also implicitly convert a reference to a derived class to a reference to a base class.

The following example demonstrates a standard conversion from a pointer to a derived class to a pointer to a base class:

```
#include <iostream>
using namespace std;

class Base {
public:
    char* name;
    void display() {
        cout << name << endl;
    }
};
```

280  z/OS V1R13.0 XL C/C++ Language Reference
class Derived: public Base {
    public:
        char* name;
        void display() {
            cout << name << ", " << Base::name << endl;
        }
};

int main() {
    Derived d;
    d.name = "Derived Class";
    d.Base::name = "Base Class";

    Derived* dptr = &d;

    // standard conversion from Derived* to Base*
    Base* bptr = dptr;

    // call Base::display()
    bptr->display();
}

The following is the output of the above example:
Base Class

The statement Base* bptr = dptr converts a pointer of type Derived to a pointer of type Base.

The reverse case is not allowed. You cannot implicitly convert a pointer or a reference to a base class object to a pointer or reference to a derived class. For example, the compiler will not allow the following code if the classes Base and Class are defined as in the above example:

int main() {
    Base b;
    b.name = "Base class";

    Derived* dptr = &b;
}

The compiler will not allow the statement Derived* dptr = &b because the statement is trying to implicitly convert a pointer of type Base to a pointer of type Derived.

If a member of a derived class and a member of a base class have the same name, the base class member is hidden in the derived class. If a member of a derived class has the same name as a base class, the base class name is hidden in the derived class.

Inherited member access

The following sections discuss the access rules affecting a protected nonstatic base class member and how to declare a derived class using an access specifier:

- "Protected members” on page 282
- "Access control of base class members” on page 283
Protected members

A protected nonstatic base class member can be accessed by members and friends of any classes derived from that base class by using one of the following:

- A pointer to a directly or indirectly derived class
- A reference to a directly or indirectly derived class
- An object of a directly or indirectly derived class

If a class is derived privately from a base class, all protected base class members become private members of the derived class.

If you reference a protected nonstatic member \( x \) of a base class \( A \) in a friend or a member function of a derived class \( B \), you must access \( x \) through a pointer to, reference to, or object of a class derived from \( A \). However, if you are accessing \( x \) to create a pointer to member, you must qualify \( x \) with a nested name specifier that names the derived class \( B \). The following example demonstrates this:

```c++
class A {
  public:
    protected:
      int i;
};

class B : public A {
  friend void f(A*, B*);
  void g(A*);
};

void f(A* pa, B* pb) {
  // pa->i = 1;
  pb->i = 2;
  // int A::* point_i = &A::i;
  int A::* point_i2 = &B::i;
}

void B::g(A* pa) {
  // pa->i = 1;
  i = 2;
  // int A::* point_i = &A::i;
  int A::* point_i2 = &B::i;
}

void h(A* pa, B* pb) {
  // pa->i = 1;
  // pb->i = 2;
}

int main() {
}
```

Class \( A \) contains one protected data member, an integer \( i \). Because \( B \) derives from \( A \), the members of \( B \) have access to the protected member of \( A \). Function \( f() \) is a friend of class \( B \):

- The compiler would not allow \( pa->i = 1 \) because \( pa \) is not a pointer to the derived class \( B \).
- The compiler would not allow \( int A::* point_i = &A::i \) because \( i \) has not been qualified with the name of the derived class \( B \).
Function \( g() \) is a member function of class \( B \). The previous list of remarks about which statements the compiler would and would not allow apply for \( g() \) except for the following:

- The compiler allows \( i = 2 \) because it is equivalent to \( \text{this->}i = 2 \).

Function \( h() \) cannot access any of the protected members of \( A \) because \( h() \) is neither a friend or a member of a derived class of \( A \).

**Access control of base class members**

When you declare a derived class, an access specifier can precede each base class in the base list of the derived class. This does not alter the access attributes of the individual members of a base class as seen by the base class, but allows the derived class to restrict the access control of the members of a base class.

You can derive classes using any of the three access specifiers:

- **Public**: In a public base class, public and protected members of the base class remain public and protected members of the derived class.
- **Protected**: In a protected base class, public and protected members of the base class are protected members of the derived class.
- **Private**: In a private base class, public and protected members of the base class become private members of the derived class.

In all cases, private members of the base class remain private. Private members of the base class cannot be used by the derived class unless friend declarations within the base class explicitly grant access to them.

In the following example, class \( d \) is derived publicly from class \( b \). Class \( b \) is declared a public base class by this declaration.

```cpp
class b {};
class d : public b // public derivation
{};
```

You can use both a structure and a class as base classes in the base list of a derived class declaration:

- If the derived class is declared with the keyword `class`, the default access specifier in its base list specifiers is private.
- If the derived class is declared with the keyword `struct`, the default access specifier in its base list specifiers is public.

In the following example, private derivation is used by default because no access specifier is used in the base list and the derived class is declared with the keyword `class`:

```cpp
struct B
{};
class D : B // private derivation
{};
```

Members and friends of a class can implicitly convert a pointer to an object of that class to a pointer to either:

- A direct private base class
- A protected base class (either direct or indirect)
The using declaration and class members

A using declaration in a definition of a class A allows you to introduce a name of a data member or member function from a base class of A into the scope of A.

You would need a using declaration in a class definition if you want to create a set of member functions from base and derived classes, or you want to change the access of a class member.

using declaration syntax

```
using typename ::nested_name_specifier::unqualified_id;
```

A using declaration in a class A may name one of the following:

- A member of a base class of A
- A member of an anonymous union that is a member of a base class of A
- An enumerator for an enumeration type that is a member of a base class of A

The following example demonstrates this:

```
struct Z {
    int g();
};

struct A {
    void f();
    enum E {e};
    union {int u;};
};

struct B:A {
    using A::f;
    using A::e;
    using A::u;
    // using Z::g;
};
```

The compiler would not allow the using declaration using Z::g because Z is not a base class of A.

A using declaration cannot name a template. For example, the compiler will not allow the following:

```
struct A {
    template<class T> void f(T);
};

struct B:A {
    using A::f<int>;
};
```

Every instance of the name mentioned in a using declaration must be accessible. The following example demonstrates this:

```
struct A {
    private:
        void f(int);
    public:
        int f();
```
protected:
    void g();
};

struct B : A {
    // using A::f;
    using A::g;
};

The compiler would not allow the using declaration using A::f because void A::f(int) is not accessible from B even though int A::f() is accessible.

Overloading member functions from base and derived classes

A member function named f in a class A will hide all other members named f in the base classes of A, regardless of return types or arguments. The following example demonstrates this:

struct A {
    void f() {}
};

struct B : A {
    void f(int) {}
};

int main() {
    B obj_B;
    obj_B.f(3);
    // obj_B.f();
}

The compiler would not allow the function call obj_B.f() because the declaration of void B::f(int) has hidden A::f().

To overload, rather than hide, a function of a base class A in a derived class B, you introduce the name of the function into the scope of B with a using declaration. The following example is the same as the previous example except for the using declaration using A::f:

struct A {
    void f() {}
};

struct B : A {
    using A::f;
    void f(int) {}
};

int main() {
    B obj_B;
    obj_B.f(3);
    obj_B.f();
}

Because of the using declaration in class B, the name f is overloaded with two functions. The compiler will now allow the function call obj_B.f().

You can overload virtual functions in the same way. The following example demonstrates this:
```cpp
#include <iostream>
using namespace std;

struct A {
  virtual void f() { cout << "void A::f()" << endl; }
  virtual void f(int) { cout << "void A::f(int)" << endl; }
};

struct B : A {
  using A::f;
  void f(int) { cout << "void B::f(int)" << endl; }
};

int main() {
  B obj_B;
  B* pb = &obj_B;
  pb->f(3);
  pb->f();
}
```

The following is the output of the above example:

void B::f(int)
void A::f()

Suppose that you introduce a function \( f \) from a base class \( A \) a derived class \( B \) with a `using` declaration, and there exists a function named \( B::f \) that has the same parameter types as \( A::f \). Function \( B::f \) will hide, rather than conflict with, function \( A::f \). The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {
  void f() { }
  void f(int) { cout << "void A::f(int)" << endl; }
};

struct B : A {
  using A::f;
  void f(int) { cout << "void B::f(int)" << endl; }
};

int main() {
  B obj_B;
  obj_B.f(3);
}
```

The following is the output of the above example:

void B::f(int)

### Changing the access of a class member

Suppose class \( B \) is a direct base class of class \( A \). To restrict access of class \( B \) to the members of class \( A \), derive \( B \) from \( A \) using either the access specifiers `protected` or `private`.

To increase the access of a member \( x \) of class \( A \) inherited from class \( B \), use a `using` declaration. You cannot restrict the access to \( x \) with a `using` declaration. You may increase the access of the following members:
• A member inherited as private. (You cannot increase the access of a member declared as private because a using declaration must have access to the member's name.)

• A member either inherited or declared as protected

The following example demonstrates this:

```cpp
struct A {
    protected:
    int y;
    public:
    int z;
};

struct B : private A {
};

struct C : private A {
    public:
    using A::y;
    using A::z;
};

struct D : private A {
    protected:
    using A::y;
    using A::z;
};

struct E : D {
    void f() {
        y = 1;
        z = 2;
    }
};

struct F : A {
    public:
    using A::y;
    private:
    using A::z;
};

int main() {
    B obj_B;
    // obj_B.y = 3;
    // obj_B.z = 4;

    C obj_C;
    obj_C.y = 5;
    obj_C.z = 6;

    D obj_D;
    // obj_D.y = 7;
    // obj_D.z = 8;

    F obj_F;
    obj_F.y = 9;
    obj_F.z = 10;
}
```

The compiler would not allow the following assignments from the above example:

• obj_B.y = 3 and obj_B.z = 4: Members y and z have been inherited as private.

• obj_D.y = 7 and obj_D.z = 8: Members y and z have been inherited as private, but their access have been changed to protected.

The compiler allows the following statements from the above example:
• \( y = 1 \) and \( z = 2 \) in \( D::f() \): Members \( y \) and \( z \) have been inherited as private, but their access have been changed to protected.
• \( \text{obj}_C.y = 5 \) and \( \text{obj}_C.z = 6 \): Members \( y \) and \( z \) have been inherited as private, but their access have been changed to protected.
• \( \text{obj}_F.y = 9 \): The access of member \( y \) has been changed from protected to public.
• \( \text{obj}_F.z = 10 \): The access of member \( z \) is still public. The private using declaration using \( A::z \) has no effect on the access of \( z \).

Multiple inheritance

You can derive a class from any number of base classes. Deriving a class from more than one direct base class is called multiple inheritance.

In the following example, classes A, B, and C are direct base classes for the derived class X:

```cpp
class A { /* ... */ };
class B { /* ... */ };
class C { /* ... */ };
class X : public A, private B, public C { /* ... */ };
```

The following inheritance graph describes the inheritance relationships of the above example. An arrow points to the direct base class of the class at the tail of the arrow:

```
A       B       C
   ↑      ↑      ↑
   ↓      ↓      ↓
   X
```

The order of derivation is relevant only to determine the order of default initialization by constructors and cleanup by destructors.

A direct base class cannot appear in the base list of a derived class more than once:

```cpp
class B1 { /* ... */ }; // direct base class
class D : public B1, private B1 { /* ... */ }; // error
```

However, a derived class can inherit an indirect base class more than once, as shown in the following example:

```
L
  ↑
B2
  ↑
B3
  ↑
D
```
class L { /* ... */ }; // indirect base class
class B2 : public L { /* ... */ }; 
class B3 : public L { /* ... */ }; 
class D : public B2, public B3 { /* ... */ }; // valid

In the above example, class D inherits the indirect base class L once through class B2 and once through class B3. However, this may lead to ambiguities because two subobjects of class L exist, and both are accessible through class D. You can avoid this ambiguity by referring to class L using a qualified class name. For example:

B2::L

or

B3::L.

You can also avoid this ambiguity by using the base specifier virtual to declare a base class, as described in "Derivation" on page 278.

Virtual base classes

Suppose you have two derived classes B and C that have a common base class A, and you also have another class D that inherits from B and C. You can declare the base class A as virtual to ensure that B and C share the same subobject of A.

In the following example, an object of class D has two distinct subobjects of class L, one through class B1 and another through class B2. You can use the keyword virtual in front of the base class specifiers in the base lists of classes B1 and B2 to indicate that only one subobject of type L, shared by class B1 and class B2, exists.

For example:

```
class L { /* ... */ }; // indirect base class
class B1 : virtual public L { /* ... */ }; 
class B2 : virtual public L { /* ... */ }; 
class D : public B1, public B2 { /* ... */ }; // valid
```

Using the keyword virtual in this example ensures that an object of class D inherits only one subobject of class L.

A derived class can have both virtual and nonvirtual base classes. For example:
class V { /* ... */ };
class B1 : virtual public V { /* ... */ };
class B2 : virtual public V { /* ... */ };
class B3 : public V { /* ... */ };
class X : public B1, public B2, public B3 { /* ... */ }
;
In the above example, class X has two subobjects of class V, one that is shared by classes B1 and B2 and one through class B3.

Related reference
"Derivation" on page 278

Multiple access

In an inheritance graph containing virtual base classes, a name that can be reached through more than one path is accessed through the path that gives the most access.

For example:

```cpp
class L {
public:
  void f();
};
class B1 : private virtual L {
};
class B2 : public virtual L {
};
class D : public B1, public B2 {
  public:
    void f() {
      // L::f() is accessed through B2
      // and is public
      L::f();
    }
};
```

In the above example, the function f() is accessed through class B2. Because class B2 is inherited publicly and class B1 is inherited privately, class B2 offers more access.

Related reference
"Member access" on page 268
"Protected members" on page 282
"Access control of base class members" on page 283

Ambiguous base classes

When you derive classes, ambiguities can result if base and derived classes have members with the same names. Access to a base class member is ambiguous if you use a name or qualified name that does not
refer to a unique function or object. The declaration of a member with an ambiguous name in a derived class is not an error. The ambiguity is only flagged as an error if you use the ambiguous member name.

For example, suppose that two classes named \texttt{A} and \texttt{B} both have a member named \texttt{x}, and a class named \texttt{C} inherits from both \texttt{A} and \texttt{B}. An attempt to access \texttt{x} from class \texttt{C} would be ambiguous. You can resolve ambiguity by qualifying a member with its class name using the scope resolution (\texttt{::}) operator.

```
CCNX14G

```
int main() {
    C i;
    i.f();
}

The assignment \( x = 0 \) in function \( C::f() \) is not ambiguous because the declaration \( B::x \) has hidden \( A::x \). However, the compiler will warn you that deriving \( C \) from \( A \) is redundant because you already have access to the subobject \( A \) through \( B \).

A base class declaration can be hidden along one path in the inheritance graph and not hidden along another path. The following example demonstrates this:

```c
struct A { int x; }
struct B { int y; }
struct C: A, virtual B { }
struct D: A, virtual B {
    int x;
    int y;
};
struct E: C, D { }

int main() {
    E e;
    // e.x = 1;
    e.y = 2;
}
```

The assignment \( e.x = 1 \) is ambiguous. The declaration \( D::x \) hides \( A::x \) along the path \( D::A::x \), but it does not hide \( A::x \) along the path \( C::A::x \). Therefore the variable \( x \) could refer to either \( D::x \) or \( A::x \). The assignment \( e.y = 2 \) is not ambiguous. The declaration \( D::y \) hides \( B::y \) along both paths \( D::B::y \) and \( C::B::y \) because \( B \) is a virtual base class.

Ambiguity and using declarations

Suppose you have a class named \( C \) that inherits from a class named \( A \), and \( x \) is a member name of \( A \). If you use a using declaration to declare \( A::x \) in \( C \), then \( x \) is also a member of \( C \); \( C::x \) does not hide \( A::x \). Therefore using declarations cannot resolve ambiguities due to inherited members. The following example demonstrates this:

```c
struct A {
    int x;
};
struct B: A { }
struct C: A {
    using A::x;
};
struct D: B, C {
    void f() { x = 0; }
};

int main() {
    D d;
    d.f();
}
```

The compiler will not allow the assignment \( x = 0 \) in function \( D::f() \) because it is ambiguous. The compiler can find \( x \) in two ways: as \( B::x \) or as \( C::x \).
Unambiguous class members

The compiler can unambiguously find static members, nested types, and enumerators defined in a base class A regardless of the number of subobjects of type A an object has. The following example demonstrates this:

```c++
struct A {
    int x;
    static int s;
    typedef A* Pointer_A;
    enum { e };
};

int A::s;

struct B: A {};
struct C: A {};
struct D: B, C {
    void f() {
        s = 1;
        Pointer_A pa;
        int i = e;
        // x = 1;
    }
};

int main() {
    D d;
    d.f();
}
```

The compiler allows the assignment s = 1, the declaration Pointer_A pa, and the statement int i = e. There is only one static variable s, only one typedef Pointer_A, and only one enumerator e. The compiler would not allow the assignment x = 1 because x can be reached either from class B or class C.

Pointer conversions

Conversions (either implicit or explicit) from a derived class pointer or reference to a base class pointer or reference must refer unambiguously to the same accessible base class object. (An accessible base class is a publicly derived base class that is neither hidden nor ambiguous in the inheritance hierarchy.) For example:

```c++
class W { /* ... */};
class X : public W { /* ... */};
class Y : public W { /* ... */};
class Z : public X, public Y { /* ... */};
int main() {
    Z z;
    X* xptr = &z; // valid
    Y* yptr = &z; // valid
    W* wptr = &z; // error, ambiguous reference to class W
    // X's W or Y's W ?
}
```

You can use virtual base classes to avoid ambiguous reference. For example:

```c++
class W { /* ... */};
class X : public virtual W { /* ... */};
class Y : public virtual W { /* ... */};
class Z : public X, public Y { /* ... */};
int main() {
    Z z;
    X* xptr = &z; // valid
    Y* yptr = &z; // valid
    W* wptr = &z; // error, ambiguous reference to class W
    // X's W or Y's W ?
}```
A pointer to a member of a base class can be converted to a pointer to a member of a derived class if the following conditions are true:

- The conversion is not ambiguous. The conversion is ambiguous if multiple instances of the base class are in the derived class.
- A pointer to the derived class can be converted to a pointer to the base class. If this is the case, the base class is said to be accessible.
- Member types must match. For example suppose class A is a base class of class B. You cannot convert a pointer to member of A of type int to a pointer to member of type B of type float.
- The base class cannot be virtual.

**Overload resolution**

Overload resolution takes place after the compiler unambiguously finds a given function name. The following example demonstrates this:

```cpp
struct A {
  int f() { return 1; }
};

struct B {
  int f(int arg) { return arg; }
};

struct C: A, B {
  int g() { return f(); }
};
```

The compiler will not allow the function call to f() in C::g() because the name f has been declared both in A and B. The compiler detects the ambiguity error before overload resolution can select the base match A::f().

**Related reference**

- "Scope resolution operator :: (C++ only)" on page 121
- "Virtual base classes" on page 289

**Virtual functions**

By default, C++ matches a function call with the correct function definition at compile time. This is called static binding. You can specify that the compiler match a function call with the correct function definition at run time; this is called dynamic binding. You declare a function with the keyword virtual if you want the compiler to use dynamic binding for that specific function.

The following examples demonstrate the differences between static and dynamic binding. The first example demonstrates static binding:

```cpp
#include <iostream>
using namespace std;

struct A {
  void f() { cout << "Class A" << endl; }
};

struct B: A {
```
```cpp
void f() { cout << "Class B" << endl; }

void g(A& arg) {
    arg.f();
}

int main() {
    B x;
    g(x);
}
```

The following is the output of the above example:

Class A

When function g() is called, function A::f() is called, although the argument refers to an object of type B. At compile time, the compiler knows only that the argument of function g() will be a reference to an object derived from A; it cannot determine whether the argument will be a reference to an object of type A or type B. However, this can be determined at run time. The following example is the same as the previous example, except that A::f() is declared with the `virtual` keyword:

```cpp
#include <iostream>
using namespace std;

struct A {
    virtual void f() { cout << "Class A" << endl; }
};

struct B: A {
    void f() { cout << "Class B" << endl; }
}

void g(A& arg) {
    arg.f();
}

int main() {
    B x;
    g(x);
}
```

The following is the output of the above example:

Class B

The `virtual` keyword indicates to the compiler that it should choose the appropriate definition of f() not by the type of reference, but by the type of object that the reference refers to.

Therefore, a virtual function is a member function you may redefine for other derived classes, and can ensure that the compiler will call the redefined virtual function for an object of the corresponding derived class, even if you call that function with a pointer or reference to a base class of the object.

A class that declares or inherits a virtual function is called a polymorphic class.

You redefine a virtual member function, like any member function, in any derived class. Suppose you declare a virtual function named f in a class A, and you derive directly or indirectly from A a class named B. If you declare a function named f in class B with the same name and same parameter list as A::f, then B::f is also virtual (regardless whether or not you declare B::f with the virtual keyword) and it overrides A::f. However, if the parameter lists of A::f and B::f are different, A::f and B::f are considered different, B::f does not override A::f, and B::f is not virtual (unless you have declared it with the virtual keyword). Instead B::f hides A::f. The following example demonstrates this:
```cpp
#include <iostream>
using namespace std;

struct A {
    virtual void f() { cout << "Class A" << endl; }
};

struct B: A {
    void f(int) { cout << "Class B" << endl; }
};

struct C: B {
    void f() { cout << "Class C" << endl; }
};

int main() {
    B b; C c;
    A* pa1 = &b;
    A* pa2 = &c;
    // b.f();
    pa1->f();
    pa2->f();
}
```

The following is the output of the above example:

Class A
Class C

The function B::f is not virtual. It hides A::f. Thus the compiler will not allow the function call b.f(). The function C::f is virtual; it overrides A::f even though A::f is not visible in C.

If you declare a base class destructor as virtual, a derived class destructor will override that base class destructor, even though destructors are not inherited.

The return type of an overriding virtual function may differ from the return type of the overridden virtual function. This overriding function would then be called a *covariant virtual function*. Suppose that B::f overrides the virtual function A::f. The return types of A::f and B::f may differ if all the following conditions are met:

- The function B::f returns a reference or pointer to a class of type T, and A::f returns a pointer or a reference to an unambiguous direct or indirect base class of T.
- The const or volatile qualification of the pointer or reference returned by B::f has the same or less const or volatile qualification of the pointer or reference returned by A::f.
- The return type of B::f must be complete at the point of declaration of B::f, or it can be of type B.

The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {};

class B : private A {
    friend class D;
    friend class F;
};

A global_A;
B global_B;

struct C {
    virtual A* f() {
        cout << "A* C::f()" << endl;
        return &global_A;
```
The following is the output of the above example:
B* D::f()
B* D::f()

The statement A* ap = cp->f() calls D::f() and converts the pointer returned to type A*. The statement
B* bp = dp->f() calls D::f() as well but does not convert the pointer returned; the type returned is B*.
The compiler would not allow the declaration of the virtual function F::f() because E is not a complete
class. The compiler would not allow the declaration of the virtual function G::f() because class A is not an
accessible base class of B (unlike friend classes D and F, the definition of B does not give access to its
members for class G).

A virtual function cannot be global or static because, by definition, a virtual function is a member function
of a base class and relies on a specific object to determine which implementation of the function is called.
You can declare a virtual function to be a friend of another class.

If a function is declared virtual in its base class, you can still access it directly using the scope resolution
(::) operator. In this case, the virtual function call mechanism is suppressed and the function
implementation defined in the base class is used. In addition, if you do not override a virtual member
function in a derived class, a call to that function uses the function implementation defined in the base
class.

A virtual function must be one of the following:
• Defined
• Declared pure
• Defined and declared pure
A base class containing one or more pure virtual member functions is called an abstract class.

Related reference
"Abstract classes" on page 299

Ambiguous virtual function calls

You cannot override one virtual function with two or more ambiguous virtual functions. This can happen in a derived class that inherits from two nonvirtual bases that are derived from a virtual base class.

For example:
```cpp
class V {
public:
  virtual void f() {} 
};
class A : virtual public V {
  void f() {} 
};
class B : virtual public V {
  void f() {} 
};
// Error:
// Both A::f() and B::f() try to override V::f()
class D : public A, public B {} ;
int main() {
  D d;
  V* vptr = &d;
  // which f(), A::f() or B::f()? 
vptr->f();
}
```

The compiler will not allow the definition of class D. In class A, only A::f() will override V::f(). Similarly, in class B, only B::f() will override V::f(). However, in class D, both A::f() and B::f() will try to override V::f(). This attempt is not allowed because it is not possible to decide which function to call if a D object is referenced with a pointer to class V, as shown in the above example. Only one function can override a virtual function.

A special case occurs when the ambiguous overriding virtual functions come from separate instances of the same class type. In the following example, class D has two separate subobjects of class A:
```cpp
#include <iostream>
using namespace std;
struct A {
  virtual void f() { cout << "A::f()" << endl; }
};
struct B : A {
  void f() { cout << "B::f()" << endl; }
};
struct C : A {
  void f() { cout << "C::f()" << endl; }
};
struct D : B, C {};
int main() {
  D d;
}
```
Class D has two occurrences of class A, one inherited from B, and another inherited from C. Therefore there are also two occurrences of the virtual function A::f. The statement ap->f() calls D::B::f. However the compiler would not allow the statement dp->f() because it could either call D::B::f or D::C::f.

Virtual function access

The access for a virtual function is specified when it is declared. The access rules for a virtual function are not affected by the access rules for the function that later overrides the virtual function. In general, the access of the overriding member function is not known.

If a virtual function is called with a pointer or reference to a class object, the type of the class object is not used to determine the access of the virtual function. Instead, the type of the pointer or reference to the class object is used.

In the following example, when the function f() is called using a pointer having type B*, bptr is used to determine the access to the function f(). Although the definition of f() defined in class D is executed, the access of the member function f() in class B is used. When the function f() is called using a pointer having type D*, dptr is used to determine the access to the function f(). This call produces an error because f() is declared private in class D.

class B {
    public:
        virtual void f();
};

class D : public B {
    private:
        void f();
};

int main() {
    D dobj;
    B* bptr = &dobj;
    D* dptr = &dobj;

    // valid, virtual B::f() is public,
    // D::f() is called
    bptr->f();

    // error, D::f() is private
    dptr->f();
}

Abstract classes

An abstract class is a class that is designed to be specifically used as a base class. An abstract class contains at least one pure virtual function. You declare a pure virtual function by using a pure specifier (= 0) in the declaration of a virtual member function in the class declaration.

The following is an example of an abstract class:
Function `AB::f` is a pure virtual function. A function declaration cannot have both a pure specifier and a definition. For example, the compiler will not allow the following:

```c++
struct A {
    virtual void g() {} = 0;
};
```

You cannot use an abstract class as a parameter type, a function return type, or the type of an explicit conversion, nor can you declare an object of an abstract class. You can, however, declare pointers and references to an abstract class. The following example demonstrates this:

```c++
struct A {
    virtual void f() = 0;
};

struct B : A {
    virtual void f() {}  
};
```

Virtual member functions are inherited. A class derived from an abstract base class will also be abstract unless you override each pure virtual function in the derived class.

For example:

```c++
class AB {
public:
    virtual void f() = 0;
};

class D2 : public AB {
    void g();
};
```
int main() {
    D2 d;
}

The compiler will not allow the declaration of object d because D2 is an abstract class; it inherited the pure virtual function f() from AB. The compiler will allow the declaration of object d if you define function D2::f(), as this overrides the inherited pure virtual function AB::f(). Function AB::f() needs to be overridden if you want to avoid the abstraction of D2.

Note that you can derive an abstract class from a nonabstract class, and you can override a non-pure virtual function with a pure virtual function.

You can call member functions from a constructor or destructor of an abstract class. However, the results of calling (directly or indirectly) a pure virtual function from its constructor are undefined. The following example demonstrates this:

struct A {
    A() {
        direct();
        indirect();
    }
    virtual void direct() = 0;
    virtual void indirect() { direct(); }
};

The default constructor of A calls the pure virtual function direct() both directly and indirectly (through indirect()).

Chapter 14. Special member functions (C++ only)

The default constructor, destructor, copy constructor, and copy assignment operator are special member functions. These functions create, destroy, convert, initialize, and copy class objects.

Overview of constructors and destructors

Because classes have complicated internal structures, including data and functions, object initialization and cleanup for classes is much more complicated than it is for simple data structures. Constructors and destructors are special member functions of classes that are used to construct and destroy class objects. Construction may involve memory allocation and initialization for objects. Destruction may involve cleanup and deallocation of memory for objects.

Like other member functions, constructors and destructors are declared within a class declaration. They can be defined inline or external to the class declaration. Constructors can have default arguments. Unlike other member functions, constructors can have member initialization lists. The following restrictions apply to constructors and destructors:

- Constructors and destructors do not have return types nor can they return values.
- References and pointers cannot be used on constructors and destructors because their addresses cannot be taken.
- Constructors cannot be declared with the keyword virtual.
- Constructors and destructors cannot be declared static, const, or volatile.
- Unions cannot contain class objects that have constructors or destructors.

Constructors and destructors obey the same access rules as member functions. For example, if you declare a constructor with protected access, only derived classes and friends can use it to create class objects.

The compiler automatically calls constructors when defining class objects and calls destructors when class objects go out of scope. A constructor does not allocate memory for the class object its this pointer refers to, but may allocate storage for more objects than its class object refers to. If memory allocation is required for objects, constructors can explicitly call the new operator. During cleanup, a destructor may release objects allocated by the corresponding constructor. To release objects, use the delete operator.

Derived classes do not inherit or overload constructors or destructors from their base classes, but they do call the constructor and destructor of base classes. Destructors can be declared with the keyword virtual.

Constructors are also called when local or temporary class objects are created, and destructors are called when local or temporary objects go out of scope.

You can call member functions from constructors or destructors. You can call a virtual function, either directly or indirectly, from a constructor or destructor of a class A. In this case, the function called is the one defined in A or a base class of A, but not a function overridden in any class derived from A. This avoids the possibility of accessing an unconstructed object from a constructor or destructor. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {
  virtual void f() { cout << "void A::f()" << endl; }
  virtual void g() { cout << "void A::g()" << endl; }
  virtual void h() { cout << "void A::h()" << endl; }
};
```

© Copyright IBM Corp. 1998, 2011
struct B : A {
    virtual void f() { cout << "void B::f()" << endl; }
    B() {
        f();
        g();
        h();
    }
};

struct C : B {
    virtual void f() { cout << "void C::f()" << endl; }
    virtual void g() { cout << "void C::g()" << endl; }
    virtual void h() { cout << "void C::h()" << endl; }
};

int main() {
    C obj;
}

The following is the output of the above example:

void B::f()
void A::g()
void A::h()

The constructor of B does not call any of the functions overridden in C because C has been derived from B, although the example creates an object of type C named obj.

You can use the typeid or the dynamic_cast operator in constructors or destructors, as well as member initializers of constructors.

"new expressions (C++ only)” on page 153

Constructors

A constructor is a member function with the same name as its class. For example:

class X {
public:
    X(); // constructor for class X
};

Constructors are used to create, and can initialize, objects of their class type.

You cannot declare a constructor as virtual or static, nor can you declare a constructor as const, volatile, or const volatile.

You do not specify a return type for a constructor. A return statement in the body of a constructor cannot have a return value.

Default constructors

A default constructor is a constructor that either has no parameters, or if it has parameters, all the parameters have default values.

If no user-defined constructor exists for a class A and one is needed, the compiler implicitly declares a default parameterless constructor A::A(). This constructor is an inline public member of its class. The compiler will implicitly define A::A() when the compiler uses this constructor to create an object of type A. The constructor will have no constructor initializer and a null body.
The compiler first implicitly defines the implicitly declared constructors of the base classes and nonstatic data members of a class A before defining the implicitly declared constructor of A. No default constructor is created for a class that has any constant or reference type members.

A constructor of a class A is trivial if all the following are true:
- It is implicitly defined
- A has no virtual functions and no virtual base classes
- All the direct base classes of A have trivial constructors
- The classes of all the nonstatic data members of A have trivial constructors

If any of the above are false, then the constructor is nontrivial.

A union member cannot be of a class type that has a nontrivial constructor.

Like all functions, a constructor can have default arguments. They are used to initialize member objects. If default values are supplied, the trailing arguments can be omitted in the expression list of the constructor. Note that if a constructor has any arguments that do not have default values, it is not a default constructor.

A copy constructor for a class A is a constructor whose first parameter is of type A&, const A&, volatile A&, or const volatile A&. Copy constructors are used to make a copy of one class object from another class object of the same class type. You cannot use a copy constructor with an argument of the same type as its class; you must use a reference. You can provide copy constructors with additional parameters as long as they all have default arguments. If a user-defined copy constructor does not exist for a class and one is needed, the compiler implicitly creates a copy constructor, with public access, for that class. A copy constructor is not created for a class if any of its members or base classes have an inaccessible copy constructor.

The following code fragment shows two classes with constructors, default constructors, and copy constructors:

```cpp
class X {
public:

    // default constructor, no arguments
    X();

    // constructor
    X(int, int , int = 0);

    // copy constructor
    X(const X&);

    // error, incorrect argument type
    X(X);
};

class Y {
public:

    // default constructor with one
    // default argument
    Y( int = 0);

    // default argument
    // copy constructor
    Y(const Y&, int = 0);
};
```
Delegating constructors (C++0x)

Note: C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

Before C++0x, common initializations in multiple constructors of the same class could not be concentrated in one place in a robust, maintainable manner. To partially alleviate this problem in the existing C++ programs, you could use assignment instead of initialization or add a common initialization function.

With the delegating constructors feature, you can concentrate common initializations and post initializations in one constructor named target constructor. Delegating constructors can call the target constructor to do the initialization. A delegating constructor can also be used as the target constructor of one or more delegating constructors. You can use this feature to make programs more readable and maintainable.

Delegating constructors and target constructors present the same interface as other constructors. Target constructors do not need special handling to become the target of a delegating constructor. They are selected by overload resolution or template argument deduction. After the target constructor completes execution, the delegating constructor gets controls back.

In the following example, A(T) and A(U) both delegate to A(T,U). This example demonstrates a typical usage of placing common initializations in a single constructor.

```cpp
#include <cstdio>

template <typename T, typename U> struct A{
    const T t;
    const U u;

    static T tdef;
    static U udef;

    A(T t_): A(t_, udef) {}  // A(T) constructor
    A(U u_): A(tdef, u_) {}  // A(U) constructor
};

template <typename T, typename U> T A<T,U>::tdef;
template <typename T, typename U> U A<T,U>::udef;

int main(void){
    A<unsigned char, unsigned>::tdef = 42u & 0x0F;
    A<unsigned char, unsigned> a(42u & 0xF0);
    std::printf("%d
", a.t);
    return 0;
}
```

The output of the example is:

```
42
```

In the example, A(T) and A(U) are delegating constructors, A(T,U) is the target constructor. The constant non-static data member t is initialized with an expression involving two parameters and the operator ^ in the non-delegating constructor.
A delegating constructor can be a target constructor of another delegating constructor, thus forming a delegating chain. The first constructor invoked in the construction of an object is called principal constructor. A constructor cannot delegate to itself directly or indirectly. The compiler can detect this violation if the constructors involved in a recursive chain of delegation are all defined in one translation unit. Consider the following example:

```cpp
struct A{
    int x,y;
    A():A(42){}  // A constructor must be explicitly initialized or have a default constructor.
    A(int x_):A() {x = x_;}
};
```

In the example, there is an infinitely recursive cycle that constructor `A()` delegates to constructor `A(int x_)`, and `A(int x_)` also delegates to `A()`. The compiler issues an error to indicate the violation.

You can use the delegating constructors feature interacting with other existing techniques:

- When several constructors have the same name, name and overload resolution can determine which constructor is the target constructor.
- When using delegating constructors in a template class, the deduction of template parameters works normally.

“Extensions for C++0x compatibility” on page 495

## Explicit initialization with constructors

A class object with a constructor must be explicitly initialized or have a default constructor. Except for aggregate initialization, explicit initialization using a constructor is the only way to initialize non-static constant and reference class members.

A class object that has no user-declared constructors, no virtual functions, no private or protected non-static data members, and no base classes is called an `aggregate`. Examples of aggregates are C-style structures and unions.

You explicitly initialize a class object when you create that object. There are two ways to initialize a class object:

- Using a parenthesized expression list. The compiler calls the constructor of the class using this list as the constructor's argument list.
- Using a single initialization value and the `=` operator. Because this type of expression is an initialization, not an assignment, the assignment operator function, if one exists, is not called. The type of the single argument must match the type of the first argument to the constructor. If the constructor has remaining arguments, these arguments must have default values.

**Initializer syntax**

```
expression
expression = expression,
expression
expression
```

The following example shows the declaration and use of several constructors that explicitly initialize class objects:

```cpp
CCNX13A
```
// This example illustrates explicit initialization
// by constructor.
#include <iostream>
using namespace std;

class complx {
  double re, im;
public:

  // default constructor
  complx() : re(0), im(0) { }

  // copy constructor
  complx(const complx& c) { re = c.re; im = c.im; }

  // constructor with default trailing argument
  complx( double r, double i = 0.0 ) { re = r; im = i; }

  void display() {
    cout << "re = " << re << " im = " << im << endl;
  }
};

int main() {

  // initialize with complx(double, double)
  complx one(1);

  // initialize with a copy of one
  // using complx::complx(const complx&)
  complx two = one;

  // construct complx(3,4)
  // directly into three
  complx three = complx(3,4);

  // initialize with default constructor
  complx four;

  // complx(double, double) and construct
  // directly into five
  complx five = 5;

  one.display();
  two.display();
  three.display();
  four.display();
  five.display();
}

The above example produces the following output:
re = 1  im = 0
re = 1  im = 0
re = 3  im = 4
re = 0  im = 0
re = 5  im = 0

“Initializers” on page 93

Initialization of base classes and members

Constructors can initialize their members in two different ways. A constructor can use the arguments passed to it to initialize member variables in the constructor definition:
complx(double r, double i = 0.0) { re = r; im = i; }

308  z/OS V1R13.0 XL C/C++ Language Reference
Or a constructor can have an *initializer list* within the definition but prior to the constructor body:

```cpp
complx(double r, double i = 0) : re(r), im(i) { /* ... */ }
```

Both methods assign the argument values to the appropriate data members of the class.

**Initializer list syntax**

```
<identifier> : <class_name>(<assignment_expression>)
```

Include the initialization list as part of the constructor definition, not as part of the constructor declaration. For example:

```cpp
#include <iostream>
using namespace std;

class B1 {
    int b;
public:
    B1() { cout << "B1::B1()" << endl; };

    // inline constructor
    B1(int i) : b(i) { cout << "B1::B1(int)" << endl; }
};
class B2 {
    int b;
protected:
    B2() { cout << "B2::B2()" << endl; }

    // noninline constructor
    B2(int i);
};

// B2 constructor definition including initialization list
B2::B2(int i) : b(i) { cout << "B2::B2(int)" << endl; }

class D : public B1, public B2 {
    int d1, d2;
public:
    D(int i, int j) : B1(i+1), B2(), d1(i) {
        cout << "D1::D1(int, int)" << endl;
        d2 = j;
    }
};

int main() {
    D obj(1, 2);
}
```

The output of this example:

```
B1::B1(int)
B2::B2()
D1::D1(int, int)
```

If you do not explicitly initialize a base class or member that has constructors by calling a constructor, the compiler automatically initializes the base class or member with a default constructor. In the above example, if you leave out the call `B2()` in the constructor of class `D` (as shown below), a constructor initializer with an empty expression list is automatically created to initialize `B2`. The constructors for class `D`, shown above and below, result in the same construction of an object of class `D`:
class D : public B1, public B2 {
    int d1, d2;
public:

    // call B2() generated by compiler
    D(int i, int j) : B1(i+1), d1(i) {
        cout << "D1::D1(int, int)" " endl;
        d2 = j;
    }
};

In the above example, the compiler will automatically call the default constructor for B2().

Note that you must declare constructors as public or protected to enable a derived class to call them. For example:

class B {
    B() { }
};
class D : public B {
    // error: implicit call to private B() not allowed
    D() { }
};

The compiler does not allow the definition of D::D() because this constructor cannot access the private constructor B::B().

You must initialize the following with an initializer list: base classes with no default constructors, reference data members, non-static const data members, or a class type which contains a constant data member. The following example demonstrates this:

class A {
    public:
        A(int) { }
};
class B : public A {
    static const int i;
    const int j;
    int &k;
public:
    B(int & arg) : A(0), j(1), k(arg) { }
};

int main() {
    int x = 0;
    B obj(x);
};

The data members j and k, as well as the base class A must be initialized in the initializer list of the constructor of B.

You can use data members when initializing members of a class. The following example demonstrate this:

struct A {
    int k;
    A(int i) : k(i) { }
};
struct B : A {
    int x;
    int j;
    int &r;
    B(int i) : r(x), A(i), j(this->i), i(i) { }
};
The constructor \( B(i) \) initializes the following:

- \( B::r \) to refer to \( B::x \)
- Class \( A \) with the value of the argument to \( B(i) \)
- \( B::j \) with the value of \( B::i \)
- \( B::i \) with the value of the argument to \( B(i) \)

You can also call member functions (including virtual member functions) or use the operators \texttt{typeid} or \texttt{dynamic_cast} when initializing members of a class. However if you perform any of these operations in a member initialization list before all base classes have been initialized, the behavior is undefined. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

struct A {
    int i;
    A(int arg) : i(arg) {
        cout << "Value of i: " << i << endl;
    }
};

struct B : A {
    int j;
    int f() { return i; }
    B();
};

B::B() : A(f()), j(1234) {
    cout << "Value of j: " << j << endl;
}

int main() {
    B obj;
}
```

The output of the above example would be similar to the following:

```
Value of i: 8
Value of j: 1234
```

The behavior of the initializer \( A(f()) \) in the constructor of \( B \) is undefined. The run time will call \( B::f() \) and try to access \( A::i \) even though the base \( A \) has not been initialized.

The following example is the same as the previous example except that the initializers of \( B::B() \) have different arguments:

```cpp
#include <iostream>
using namespace std;

struct A {
    int i;
    A(int arg) : i(arg) {
        cout << "Value of i: " << i << endl;
    }
};

struct B : A {
    int j;
    int f() { return i; }
    B();
};

B::B() : A(5678), j(f()) {
    cout << "Value of j: " << j << endl;
}
```

Chapter 14. Special member functions (C++ only) 311
```c
int main() {
    B obj;
}
```

The following is the output of the above example:
Value of i: 5678
Value of j: 5678

The behavior of the initializer \( j(f()) \) in the constructor of B is well-defined. The base class A is already initialized when \( B::j \) is initialized.

If the delegating constructors feature is enabled, initialization can only be done within the non-delegating constructor. In other words, a delegating constructor cannot both delegate and initialize. Consider the following example:
```c
struct A{
    int x,y;
    A(int x):x(x),y(0){}
    /* the following statement is not allowed */
    A():y(0),A(42) {}
}
```

Constructor A() delegates to A(int x), but A() also does the initialization, which is not permitted. The compiler issues an error to indicate the violation.

For more information, see "Delegating constructors (C++0x)" on page 306

"The typeid operator (C++ only)" on page 127
"The dynamic_cast operator (C++ only)" on page 151

Constructors execution order of class objects

When a class object is created using constructors, the execution order of constructors is:
1. Constructors of Virtual base classes are executed, in the order that they appear in the base list.
2. Constructors of nonvirtual base classes are executed, in the declaration order.
3. Constructors of class members are executed in the declaration order (regardless of their order in the initialization list).
4. The body of the constructor is executed.

The following example demonstrates these:
```c
#include <iostream>
using namespace std;
struct V {
    V() { cout << "V()" << endl; }
};
struct V2 {
    V2() { cout << "V2()" << endl; }
};
struct A {
    A() { cout << "A()" << endl; }
};
```
struct B : virtual V {
    B() { cout << "B()" << endl; }
};
struct C : B, virtual V2 {
    C() { cout << "C()" << endl; }
};
struct D : C, virtual V {
    A obj_A;
    D() { cout << "D()" << endl; }
};
int main() {
    D d;
}

The following is the output of the above example:

V()
V2()
B()
C()
A()
D()

The above output lists the order in which the C++ run time calls the constructors to create an object of type D.

C++0x

In the class body, if the delegating process exists, user code segments in the delegating constructors are executed after the completion of the target constructor. The inner most delegating constructor is executed first, then the next enclosing delegating constructor, until the outer most enclosing delegating constructor is executed.

Example:

#include <cstdio>
using std::printf;

class X{
public:
    int i,j;
    X();
    X(int x);
    X(int x, int y);
    ~X();
};
X::X(int x):i(x),j(23) {printf("X::X(int)\n");}
X::X(int x, int y): X(x+y) { printf("X::X(int,int)\n");}
X::X():X(44,11) {printf("X::X()\n");}
X::~X() {printf("X::~X()\n");}

int main(void){
    X x;
}

The output of the example is:

X::X(int)
X::X(int,int)
X::X()
X::~X()

For more information, see “Delegating constructors (C++0x)” on page 306.
Destructors

Destructors are usually used to deallocate memory and do other cleanup for a class object and its class members when the object is destroyed. A destructor is called for a class object when that object passes out of scope or is explicitly deleted.

A destructor is a member function with the same name as its class prefixed by a ~ (tilde). For example:

```cpp
class X {
public:
    // Constructor for class X
    X();
    // Destructor for class X
    ~X();
};
```

A destructor takes no arguments and has no return type. Its address cannot be taken. Destructors cannot be declared const, volatile, const volatile or static. A destructor can be declared virtual or pure virtual.

If no user-defined destructor exists for a class and one is needed, the compiler implicitly declares a destructor. This implicitly declared destructor is an inline public member of its class.

The compiler will implicitly define an implicitly declared destructor when the compiler uses the destructor to destroy an object of the destructor's class type. Suppose a class A has an implicitly declared destructor. The following is equivalent to the function the compiler would implicitly define for A:

```cpp
A::~A() { }
```

The compiler first implicitly defines the implicitly declared destructors of the base classes and nonstatic data members of a class A before defining the implicitly declared destructor of A.

A destructor of a class A is trivial if all the following are true:
- It is implicitly defined
- All the direct base classes of A have trivial destructors
- The classes of all the nonstatic data members of A have trivial destructors

If any of the above are false, then the destructor is nontrivial.

A union member cannot be of a class type that has a nontrivial destructor.

Class members that are class types can have their own destructors. Both base and derived classes can have destructors, although destructors are not inherited. If a base class A or a member of A has a destructor, and a class derived from A does not declare a destructor, a default destructor is generated.

The default destructor calls the destructors of the base class and members of the derived class.

The destructors of base classes and members are called in the reverse order of the completion of their constructor:
1. The destructor for a class object is called before destructors for members and bases are called.
2. Destructors for nonstatic members are called before destructors for base classes are called.
Destructors for nonvirtual base classes are called before destructors for virtual base classes are called.

When an exception is thrown for a class object with a destructor, the destructor for the temporary object thrown is not called until control passes out of the catch block.

Destructors are implicitly called when an automatic object (a local object that has been declared auto or register, or not declared as static or extern) or temporary object passes out of scope. They are implicitly called at program termination for constructed external and static objects. Destructors are invoked when you use the delete operator for objects created with the new operator.

For example:

```cpp
#include <string>

class Y {
private:
    char * string;
    int number;
public:
    // Constructor
    Y(const char*, int);
    // Destructor
    ~Y() { delete[] string; }
};

// Define class Y constructor
Y::Y(const char* n, int a) {
    string = strcpy(new char[strlen(n) + 1], n);
    number = a;
}

int main () {
    // Create and initialize
    // object of class Y
    Y yobj = Y("somestring", 10);
    // ...
    // Destructor ~Y is called before
    // control returns from main()
}
```

You can use a destructor explicitly to destroy objects, although this practice is not recommended. However to destroy an object created with the placement new operator, you can explicitly call the object's destructor. The following example demonstrates this:

```cpp
#include <new>
#include <iostream>
using namespace std;
class A {
public:
    A() { cout << "A::A()" << endl; }
    ~A() { cout << "A::~A()" << endl; }
};

int main () {
    char* p = new char[sizeof(A)];
    A* ap = new (p) A;
    ap->A::~A();
    delete [] p;
}
```
The statement `A* ap = new (p) A` dynamically creates a new object of type `A` not in the free store but in the memory allocated by `p`. The statement `delete [] p` will delete the storage allocated by `p`, but the run time will still believe that the object pointed to by `ap` still exists until you explicitly call the destructor of `A` (with the statement `ap->A::~A()`).

### Pseudo-destructors

A *pseudo-destructor* is a destructor of a nonclass type.

#### Pseudo-destructor syntax

```
[ nested_name_specifier ]:: ~type_name
```

The following example calls the pseudo destructor for an integer type:

```cpp
typedef int I;
int main() {
  I x = 10;
  x.I::~I();
  x = 20;
}
```

The call to the pseudo destructor, `x.I::~I()`, has no effect at all. Object `x` has not been destroyed; the assignment `x = 20` is still valid. Because pseudo destructors require the syntax for explicitly calling a destructor for a nonclass type to be valid, you can write code without having to know whether or not a destructor exists for a given type.

- “Scope of class names” on page 249

### User-defined conversions

*User-defined conversions* allow you to specify object conversions with constructors or with conversion functions. User-defined conversions are implicitly used in addition to standard conversions for conversion of initializers, functions arguments, function return values, expression operands, expressions controlling iteration, selection statements, and explicit type conversions.

There are two types of user-defined conversions:

- Conversion constructors
- Conversion functions

The compiler can use only one user-defined conversion (either a conversion constructor or a conversion function) when implicitly converting a single value. The following example demonstrates this:

```cpp
class A {
  int x;
public:
  operator int() { return x; }
};

class B {
  A y;
public:
```
operator A() { return y; }
};

int main () {
    B b_obj;
    // int i = b_obj;
    int j = A(b_obj);
}

The compiler would not allow the statement int i = b_obj. The compiler would have to implicitly convert b_obj into an object of type A (with B::operator A()), then implicitly convert that object to an integer (with A::operator int()). The statement int j = A(b_obj) explicitly converts b_obj into an object of type A, then implicitly converts that object to an integer.

User-defined conversions must be unambiguous, or they are not called. A conversion function in a derived class does not hide another conversion function in a base class unless both conversion functions convert to the same type. Function overload resolution selects the most appropriate conversion function. The following example demonstrates this:

class A {
    int a_int;
    char* a_carp;
public:
    operator int() { return a_int; }
    operator char*() { return a_carp; }
};

class B : public A {
    float b_float;
    char* b_carp;
public:
    operator float() { return b_float; }
    operator char*() { return b_carp; }
};

int main () {
    B b_obj;
    // long a = b_obj;
    char* c_p = b_obj;
}

The compiler would not allow the statement long a = b_obj. The compiler could either use A::operator int() or B::operator float() to convert b_obj into a long. The statement char* c_p = b_obj uses B::operator char*() to convert b_obj into a char* because B::operator char*() hides A::operator char*().

When you call a constructor with an argument and you have not defined a constructor accepting that argument type, only standard conversions are used to convert the argument to another argument type acceptable to a constructor for that class. No other constructors or conversions functions are called to convert the argument to a type acceptable to a constructor defined for that class. The following example demonstrates this:

class A {
public:
    A() {}
    A(int) {} 
};

int main() {
    A a1 = 1.234;
    // A mooocow = "text string";
}
The compiler allows the statement `A a1 = 1.234`. The compiler uses the standard conversion of converting 1.234 into an `int`, then implicitly calls the converting constructor `A(int)`. The compiler would not allow the statement `A mooCow = "text string"`; converting a text string to an integer is not a standard conversion.

**Conversion constructors**

A *conversion constructor* is a single-parameter constructor that is declared without the function specifier `explicit`. The compiler uses conversion constructors to convert objects from the type of the first parameter to the type of the conversion constructor's class. The following example demonstrates this:

```cpp
class Y {
   int a, b;
   char* name;
   public:
      Y(int i) { };
      Y(const char* n, int j = 0) { };
};

void add(Y) { };

int main() {
   
   // equivalent to
   // obj1 = Y(2)
   Y obj1 = 2;

   // equivalent to
   // obj2 = Y("somestring",0)
   Y obj2 = "somestring";

   // equivalent to
   // obj1 = Y(10)
   obj1 = 10;

   // equivalent to
   // add(Y(5))
   add(5);
}
```

The above example has the following two conversion constructors:

- `Y(int i)` which is used to convert integers to objects of class `Y`.
- `Y(const char* n, int j = 0)` which is used to convert pointers to strings to objects of class `Y`.

The compiler will not implicitly convert types as demonstrated above with constructors declared with the `explicit` keyword. The compiler will only use explicitly declared constructors in `new` expressions, the `static_cast` expressions and explicit casts, and the initialization of bases and members. The following example demonstrates this:

```cpp
class A {
   public:
      explicit A() { };
      explicit A(int) { };
};

int main() {
   A z;
   // A y = 1;
   A x = A(1);
   A w(1);
   A* v = new A(1);
   A u = (A)1;
   A t = static_cast<A>(1);
}
```
The compiler would not allow the statement `Ay = 1` because this is an implicit conversion; class `A` has no conversion constructors.

A copy constructor is a conversion constructor.

**Related reference**
- "new expressions (C++ only)" on page 153
- "The static_cast operator (C++ only)" on page 148

**The explicit specifier**

The **explicit** function specifier controls unwanted implicit type conversions. It can only be used in declarations of constructors within a class declaration. For example, except for the default constructor, the constructors in the following class are conversion constructors.

```cpp
class A
{
  public:
    A();
    A(int);
    A(const char*, int = 0);
};
```

The following declarations are legal.

```cpp
A c = 1;
A d = "Venditti";
```

The first declaration is equivalent to `A c = A(1)`.

If you declare the constructor of the class with the `explicit` keyword, the previous declarations would be illegal.

For example, if you declare the class as:

```cpp
class A
{
  public:
    explicit A();
    explicit A(int);
    explicit A(const char*, int = 0);
};
```

You can only assign values that match the values of the class type.

For example, the following statements are legal:

```cpp
A a1;
A a2 = A(1);
A a3(1);
A a4 = A("Venditti");
A* p = new A(1);
A a5 = (A)1;
A a6 = static_cast<A>(1);
```

**Related reference**
- "Conversion constructors" on page 318

**Conversion functions**

You can define a member function of a class, called a **conversion function**, that converts from the type of its class to another specified type.
A conversion function that belongs to a class X specifies a conversion from the class type X to the type specified by the conversion_type. The following code fragment shows a conversion function called operator int():

```cpp
class Y {
   int b;
public:
   operator int();
};
Y::operator int() {
   return b;
}
```

void f(Y obj) {
   int i = int(obj);
   int j = (int)obj;
   int k = i + obj;
}

All three statements in function f(Y) use the conversion function Y::operator int().

Classes, enumerations, typedef names, function types, or array types cannot be declared or defined in the conversion_type. You cannot use a conversion function to convert an object of type A to type A, to a base class of A, or to void.

Conversion functions have no arguments, and the return type is implicitly the conversion type. Conversion functions can be inherited. You can have virtual conversion functions but not static ones.

**Related reference**

"Conversion constructors" on page 318

---

### Copy constructors

The copy constructor lets you create a new object from an existing one by initialization. A copy constructor of a class A is a non-template constructor in which the first parameter is of type A&, const A&, volatile A&, or const volatile A&, and the rest of its parameters (if there are any) have default values.

If you do not declare a copy constructor for a class A, the compiler will implicitly declare one for you, which will be an inline public member.

The following example demonstrates implicitly defined and user-defined copy constructors:

```cpp
#include <iostream>
using namespace std;

struct A {
   int i;
   A() : i(10) { }
};

struct B {
   int j;
   B() : j(20) { }
```
cout << "Constructor B(), j = " << j << endl; }
B(B& arg) : j(arg.j) {
    cout << "Copy constructor B(B&), j = " << j << endl; }
B(const B&, int val = 30) : j(val) {
    cout << "Copy constructor B(const B&, int), j = " << j << endl; }
};

struct C {
    C() {} 
    C(C&) {} 
};

int main() {
    A a;
    A a1(a);
    B b;
    const B b_const;
    B b1(b);
    B b2(b_const);
    const C c_const;
    // C c1(c_const);
}

The following is the output of the above example:
Constructor B(), j = 20
Constructor B(), j = 20
Copy constructor B(B&), j = 20
Copy constructor B(const B&, int), j = 30

The statement A a1(a) creates a new object from a with an implicitly defined copy constructor. The statement B b1(b) creates a new object from b with the user-defined copy constructor B::B(B&). The statement B b2(b_const) creates a new object with the copy constructor B::B(const B&, int). The compiler would not allow the statement C c1(c_const) because a copy constructor that takes as its first parameter an object of type const C& has not been defined.

The implicitly declared copy constructor of a class A will have the form A::A(const A&) if the following are true:
• The direct and virtual bases of A have copy constructors whose first parameters have been qualified with const or const volatile
• The nonstatic class type or array of class type data members of A have copy constructors whose first parameters have been qualified with const or const volatile

If the above are not true for a class A, the compiler will implicitly declare a copy constructor with the form A::A(A&).

The compiler cannot allow a program in which the compiler must implicitly define a copy constructor for a class A and one or more of the following are true:
• Class A has a nonstatic data member of a type which has an inaccessible or ambiguous copy constructor.
• Class A is derived from a class which has an inaccessible or ambiguous copy constructor.

The compiler will implicitly define an implicitly declared constructor of a class A if you initialize an object of type A or an object derived from class A.
An implicitly defined copy constructor will copy the bases and members of an object in the same order that a constructor would initialize the bases and members of the object.

"Overview of constructors and destructors" on page 303

Copy assignment operators

The *copy assignment operator* lets you create a new object from an existing one by initialization. A copy assignment operator of a class A is a nonstatic non-template member function that has one of the following forms:

- `A::operator=(A)`
- `A::operator=(A&)`
- `A::operator=(const A&)`
- `A::operator=(volatile A&)`
- `A::operator=(const volatile A&)`

If you do not declare a copy assignment operator for a class A, the compiler will implicitly declare one for you which will be inline public.

The following example demonstrates implicitly defined and user-defined copy assignment operators:

```cpp
#include <iostream>
using namespace std;

struct A {
    A& operator=(const A&) {
        cout << "A::operator=(const A&)
            " << endl;
        return *this;
    }

    A& operator=(A&) {
        cout << "A::operator=(A&)
            " << endl;
        return *this;
    }

    A& operator=(volatile A&) {
        cout << "A::operator=(volatile A&)
            " << endl;
        return *this;
    }

    A& operator=(const volatile A&) {
        cout << "A::operator=(const volatile A&)
            " << endl;
        return *this;
    }
}

class B {
    A a;
};

struct C {
    C& operator=(C&) {
        cout << "C::operator=(C&)
            " << endl;
        return *this;
    }

    C() {
    }
};

int main() {
    B x, y;
    x = y;

    A w, z;
    w = z;

    C i;
    const C j();
    // i = j;
}
```

The following is the output of the above example:

```
A::operator=(const A&)
A::operator=(A&)
A::operator=(volatile A&)
A::operator=(const volatile A&)
```
A::operator=(const A&)
A::operator=(A&)

The assignment x = y calls the implicitly defined copy assignment operator of B, which calls the user-defined copy assignment operator A::operator=(const A&). The assignment w = z calls the user-defined operator A::operator=(A&). The compiler will not allow the assignment i = j because an operator C::operator=(const C&) has not been defined.

The implicitly declared copy assignment operator of a class A will have the form A& A::operator=(const A&) if the following are true:

- A direct or virtual base B of class A has a copy assignment operator whose parameter is of type const B&, const volatile B&, or B.
- A non-static class type data member of type X that belongs to class A has a copy constructor whose parameter is of type const X&, const volatile X&, or X.

If the above are not true for a class A, the compiler will implicitly declare a copy assignment operator with the form A& A::operator=(A&).

The implicitly declared copy assignment operator returns a reference to the operator's argument.

The copy assignment operator of a derived class hides the copy assignment operator of its base class.

The compiler cannot allow a program in which the compiler must implicitly define a copy assignment operator for a class A and one or more of the following are true:

- Class A has a nonstatic data member of a const type or a reference type
- Class A has a nonstatic data member of a type which has an inaccessible copy assignment operator
- Class A is derived from a base class with an inaccessible copy assignment operator.

An implicitly defined copy assignment operator of a class A will first assign the direct base classes of A in the order that they appear in the definition of A. Next, the implicitly defined copy assignment operator will assign the nonstatic data members of A in the order of their declaration in the definition of A.

"Assignment operators" on page 132
Chapter 15. Templates (C++ only)

A template describes a set of related classes or set of related functions in which a list of parameters in the declaration describe how the members of the set vary. The compiler generates new classes or functions when you supply arguments for these parameters; this process is called template instantiation, and is described in detail in "Template instantiation" on page 345. This class or function definition generated from a template and a set of template parameters is called a specialization, as described in "Template specialization" on page 349.

**Template declaration syntax**

```
export template <template_parameter_list> declaration
```

The compiler accepts and silently ignores the export keyword on a template.

The template_parameter_list is a comma-separated list of template parameters, which are described in "Template parameters" on page 326.

The declaration is one of the following:
- a declaration or definition of a function or a class
- a definition of a member function or a member class of a class template
- a definition of a static data member of a class template
- a definition of a static data member of a class nested within a class template
- a definition of a member template of a class or class template

The identifier of a type is defined to be a type_name in the scope of the template declaration. A template declaration can appear as a namespace scope or class scope declaration.

The following example demonstrates the use of a class template:

```cpp
template<class T> class Key
{
    T k;
    T* kptr;
    int length;
public:
    Key(T);
    // ...
};
```

Suppose the following declarations appear later:

```cpp
Key<int> i;
Key<char*> c;
Key<mytype> m;
```

The compiler would create three instances of class Key. The following table shows the definitions of these three class instances if they were written out in source form as regular classes, not as templates:
Note that these three classes have different names. The arguments contained within the angle braces are not just the arguments to the class names, but part of the class names themselves. Key<int> and Key<char*> are class names.

**Template parameters**

There are three kinds of template parameters:

- "Type template parameters"
- "Non-type template parameters"
- "Template template parameters" on page 327

Template parameter packs can also be a kind of template parameter. For more information, see "Variadic templates (C++0x)” on page 356.

You can interchange the keywords class and typename in a template parameter declaration. You cannot use storage class specifiers (static and auto) in a template parameter declaration.

**Related reference**

"Type qualifiers” on page 74

"Lvalues and rvalues” on page 117

**Type template parameters**

Type template parameter declaration syntax

```
class typename identifier = type
```

The identifier is the name of a type.

**Related reference**

"The typename keyword” on page 369

**Non-type template parameters**

The syntax of a non-type template parameter is the same as a declaration of one of the following types:

- integral or enumeration
- pointer to object or pointer to function
- reference to object or reference to function
- pointer to member
Non-type template parameters that are declared as arrays or functions are converted to pointers or pointers to functions, respectively. The following example demonstrates this:

```cpp
template<int a[4]> struct A {};  
template<int f(int)> struct B {};  

int i;  
int g(int) { return 0;}  
A<&i> x;  
B<&g> y;
```

The type deduced from \&i is int *, and the type deduced from \&g is int (*)(int).

You may qualify a non-type template parameter with const or volatile.

You cannot declare a non-type template parameter as a floating point, class, or void type.

Non-type template parameters are not lvalues.

**Related reference**

"Type qualifiers" on page 74
"Lvalues and rvalues" on page 117

**Template template parameters**

The following example demonstrates a declaration and use of a template template parameter:

```cpp
template<template <class T> class X> class A {};  
template<class T> class B {};  
A<B> a;
```

**Default arguments for template parameters**

Template parameters may have default arguments. The set of default template arguments accumulates over all declarations of a given template. The following example demonstrates this:

```cpp
template<class T, class U = int> class A;  
template<class T = float, class U> class A;

template<class T, class U> class A {
  public:
    T x;
    U y;
};  
A<> a;
```

The type of member a.x is float, and the type of a.y is int.

You cannot give default arguments to the same template parameters in different declarations in the same scope. For example, the compiler will not allow the following:

```cpp
template<class T = char> class X;  
template<class T = char> class X { };
If one template parameter has a default argument, then all template parameters following it must also have default arguments. For example, the compiler will not allow the following:

```cpp
template<class T = char, class U, class V = int> class X {}; 
```

Template parameter U needs a default argument or the default for T must be removed.

The scope of a template parameter starts from the point of its declaration to the end of its template definition. This implies that you may use the name of a template parameter in other template parameter declarations and their default arguments. The following example demonstrates this:

```cpp
template<class T = int> class A;
template<class T = float> class B;
template<class V, V obj> class C;
// a template parameter (T) used as the default argument
// to another template parameter (U)
template<class T, class U = T> class D {}; 
```

### Naming template parameters as friends (C++0x)

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

In the C++0x standard, the extended friend declarations feature is introduced, with which you can declare template parameters as friends. This makes friend declarations inside templates easier to use.

If a friend declaration resolves to a template parameter, then you cannot use an elaborated-type-specifier in this friend declaration; otherwise, the compiler issues an error.

**Related reference**

“Friends” on page 270

### Template arguments

There are three kinds of template arguments corresponding to the three types of template parameters:

- “Template type arguments” on page 329
- “Template non-type arguments” on page 329
- “Template template arguments” on page 331

A template argument must match the type and form specified by the corresponding parameter declared in the template.

When a parameter declared in a template is a template parameter pack, it corresponds to zero or more template arguments. For more information, see “Variadic templates (C++0x)” on page 356

To use the default value of a template parameter, you omit the corresponding template argument. However, even if all template parameters have defaults, you still must use the angle brackets <>. For example, the following will yield a syntax error:

```cpp
template<class T = int> class X {}; 
X<> a;
X b;
```
The last declaration, \( X \ b \), will yield an error.

**Related reference**
- “Block/local scope” on page 2
- “No linkage” on page 8
- Bit field members
- “typedef definitions” on page 66

### Template type arguments

You cannot use one of the following as a template argument for a type template parameter:
- a local type
- a type with no linkage
- an unnamed type
- a type compounded from any of the above types

If it is ambiguous whether a template argument is a type or an expression, the template argument is considered to be a type. The following example demonstrates this:

```cpp
template<class T> void f() { }
template<int i> void f() { }

int main() {
  f<int()>();
}
```

The function call \( f<int()>() \) calls the function with \( T \) as a template argument – the compiler considers \( int() \) as a type – and therefore implicitly instantiates and calls the first \( f() \).

**Related reference**
- “Block/local scope” on page 2
- “No linkage” on page 8
- Bit field members
- “typedef definitions” on page 66

### Template non-type arguments

A non-type template argument provided within a template argument list is an expression whose value can be determined at compile time. Such arguments must be constant expressions, addresses of functions or objects with external linkage, or addresses of static class members. Non-type template arguments are normally used to initialize a class or to specify the sizes of class members.

For non-type integral arguments, the instance argument matches the corresponding template parameter as long as the instance argument has a value and sign appropriate to the parameter type.

For non-type address arguments, the type of the instance argument must be of the form `identifier` or `&identifier`, and the type of the instance argument must match the template parameter exactly, except that a function name is changed to a pointer to function type before matching.

The resulting values of non-type template arguments within a template argument list form part of the template class type. If two template class names have the same template name and if their arguments have identical values, they are the same class.

In the following example, a class template is defined that requires a non-type template \( int \) argument as well as the type argument:
template<class T, int size> class Myfilebuf
{
  T* filepos;
  static int array[size];
public:
  Myfilebuf() { /* ... */ }
  ~Myfilebuf();
  advance(); // function defined elsewhere in program
};

In this example, the template argument size becomes a part of the template class name. An object of such a template class is created with both the type argument T of the class and the value of the non-type template argument size.

An object x, and its corresponding template class with arguments double and size=200, can be created from this template with a value as its second template argument:
Myfilebuf<double,200> x;

x can also be created using an arithmetic expression:
Myfilebuf<double,10*20> x;

The objects created by these expressions are identical because the template arguments evaluate identically. The value 200 in the first expression could have been represented by an expression whose result at compile time is known to be equal to 200, as shown in the second construction.

**Note:** Arguments that contain the < symbol or the > symbol must be enclosed in parentheses to prevent either symbol from being parsed as a template argument list delimiter when it is in fact being used as a relational operator. For example, the arguments in the following definition are valid:
Myfilebuf<double, (75>25)> x; // valid

The following definition, however, is not valid because the greater than operator (> is interpreted as the closing delimiter of the template argument list:
Myfilebuf<double, 75>25> x; // error

If the template arguments do not evaluate identically, the objects created are of different types:
Myfilebuf<double,200> x; // create object x of class
Myfilebuf<double,200.0> y; // error, 200.0 is a double,
 // not an int

The instantiation of y fails because the value 200.0 is of type double, and the template argument is of type int.

The following two objects:
Myfilebuf<double, 128> x
Myfilebuf<double, 512> y

are objects of separate template specializations. Referring either of these objects later with Myfilebuf<double> is an error.

A class template does not need to have a type argument if it has non-type arguments. For example, the following template is a valid class template:
template<int i> class C
{
  public:
    int k;
    C() { k = i; }
};
This class template can be instantiated by declarations such as:

```cpp
class C<100>;
class C<200>;
```

Again, these two declarations refer to distinct classes because the values of their non-type arguments differ.

- "References (C++ only)" on page 92
- "External linkage" on page 7
- "Static members" on page 264

### Template template arguments

A template argument for a template template parameter is the name of a class template.

When the compiler tries to find a template to match the template template argument, it only considers primary class templates. (A *primary template* is the template that is being specialized.) The compiler will not consider any partial specialization even if their parameter lists match that of the template template parameter. For example, the compiler will not allow the following code:

```cpp
template<class T, int i> class A {
  int x;
};
template<class T> class A<T, 5> {
  short x;
};
template<template<class T> class U> class B1 { };
B1<A> c;
```

The compiler will not allow the declaration `B1<A> c`. Although the partial specialization of `A` seems to match the template template parameter `U` of `B1`, the compiler considers only the primary template of `A`, which has different template parameters than `U`.

The compiler considers the partial specializations based on a template template argument once you have instantiated a specialization based on the corresponding template template parameter. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

template<class T, class U> class A {
  int x;
};
template<class U> class A<int, U> {
  short x;
};
template<template<class T, class U> class V> class B { 
  V<int, char> i;
  V<char, char> j;
};
B<A> c;
```
int main() {
    cout << typeid(c.i.x).name() << endl;
    cout << typeid(c.j.x).name() << endl;
}

The following is the output of the above example:
short
int

The declaration V<int, char> i uses the partial specialization while the declaration V<char, char> j uses the primary template.

Class templates

The relationship between a class template and an individual class is like the relationship between a class and an individual object. An individual class defines how a group of objects can be constructed, while a class template defines how a group of classes can be generated.

Note the distinction between the terms class template and template class:

Class template
is a template used to generate template classes. You cannot declare an object of a class template.

Template class
is an instance of a class template.

A template definition is identical to any valid class definition that the template might generate, except for the following:

• The class template definition is preceded by
template< template-parameter-list >

where template-parameter-list is a comma-separated list of one or more of the following kinds of template parameters:
– type
– non-type
– template

• Types, variables, constants and objects within the class template can be declared using the template parameters as well as explicit types (for example, int or char).

Template parameter packs can also be a kind of parameter for class templates. For more information, see “Variadic templates (C++0x)” on page 356.

A class template can be declared without being defined by using an elaborated type specifier. For example:
template<class L, class T> class Key;
This reserves the name as a class template name. All template declarations for a class template must have the same types and number of template arguments. Only one template declaration containing the class definition is allowed.

By using template parameter packs, template declarations for a class template can have fewer or more arguments than the number of parameters specified in the class template.

Note: When you have nested template argument lists, you must have a separating space between the > at the end of the inner list and the > at the end of the outer list. Otherwise, there is an ambiguity between the extraction operator >> and two template list delimiters >.

```
template<class L, class T> class Key { /* ... */};
```

```
template<class L> class Vector { /* ... */ }; 
```

```
int main ()
{
    class Key <int, Vector<int> > my_key_vector;
    // implicitly instantiates template
}
```

Objects and function members of individual template classes can be accessed by any of the techniques used to access ordinary class member objects and functions. Given a class template:

```
template<class T> class Vehicle
{
public:
    Vehicle() { /* ... */ } // constructor
    ~Vehicle() {}; // destructor
    T kind[16];
    T* drive();
    static void roadmap();
    // ...
};
```

and the declaration:

```
Vehicle<char> bicycle; // instantiates the template
```

the constructor, the constructed object, and the member function drive() can be accessed with any of the following (assuming the standard header file string.h is included in the program file):

```
<table>
<thead>
<tr>
<th>construct</th>
<th>Vehiclexh</th>
<th>bicycle;</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>constructor called automatically, object bicycle created</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Object</th>
<th>bicycle</th>
</tr>
</thead>
<tbody>
<tr>
<td>strcpy (bicycle.kind, &quot;10 speed&quot;);</td>
<td></td>
</tr>
<tr>
<td>bicycle.kind[0] = '2';</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Function</th>
<th>drive()</th>
</tr>
</thead>
<tbody>
<tr>
<td>char* n = bicycle.drive();</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Function</th>
<th>roadmap()</th>
</tr>
</thead>
<tbody>
<tr>
<td>Vehicle&lt;char&gt;::roadmap();</td>
<td></td>
</tr>
</tbody>
</table>
```
Class template declarations and definitions

A class template must be declared before any instantiation of a corresponding template class. A class template definition can only appear once in any single translation unit. A class template must be defined before any use of a template class that requires the size of the class or refers to members of the class.

In the following example, the class template `Key` is declared before it is defined. The declaration of the pointer `keyiptr` is valid because the size of the class is not needed. The declaration of `keyi`, however, causes an error.

```cpp
template <class L> class Key; // class template declared, not defined yet
class Key<int> *keyiptr; // declaration of pointer
class Key<int> keyi; // error, cannot declare keyi without knowing size

template <class L> class Key // now class template defined
{ /* ... */ };
```

If a template class is used before the corresponding class template is defined, the compiler issues an error. A class name with the appearance of a template class name is considered to be a template class. In other words, angle brackets are valid in a class name only if that class is a template class.

The previous example uses the elaborated type specifier `class` to declare the class template `key` and the pointer `keyiptr`. The declaration of `keyiptr` can also be made without the elaborated type specifier.

```cpp
template <class L> class Key; // class template declared, not defined yet

Key<int> *keyiptr; // declaration of pointer
Key<int> keyi; // error, cannot declare keyi without knowing size

template <class L> class Key // now class template defined
{ /* ... */ };
```

In the z/OS implementation, the compiler checks the syntax of the entire template class definition when the template include files are being compiled if the TEMPINC compiler option is used, or during the original compiler pass if the NOTEMPINC compiler option is used. Any errors in the class definition are flagged. The compiler does not generate code or data until it requires a specialization. At that point it generates appropriate code and data for the specialization by using the argument list supplied.

Static data members and templates

Each class template instantiation has its own copy of any static data members. The static declaration can be of template argument type or of any defined type.

You must separately define static members. The following example demonstrates this:
template <class T> class K
{
    public:
        static T x;
    }

template <class T> T K<T>::x;

int main()
{
    K<int>::x = 0;
}

The statement template T K::x defines the static member of class K, while the statement in the main() function assigns a value to the data member for K <int>.

Related reference
“Static members” on page 264

Member functions of class templates

You may define a template member function outside of its class template definition.

When you call a member function of a class template specialization, the compiler will use the template arguments that you used to generate the class template. The following example demonstrates this:

template<class T> class X {
    public:
        T operator+(T); 
    }

template<class T> T X<T>::operator+(T arg1) {
    return arg1;
}

int main() {
    X<char> a;
    X<int> b;
    a + 'z';
    b + 4;
}

The overloaded addition operator has been defined outside of class X. The statement a + 'z' is equivalent to a.operator+('z'). The statement b + 4 is equivalent to b.operator+(4).

You can use trailing return types for template member functions, including those that have the following kinds of return types:
• Return types depending on the types of the function arguments
• Complicated return types

For more information, see “Trailing return type (C++0x)” on page 202.
Friends and templates

There are four kinds of relationships between classes and their friends when templates are involved:

- **One-to-many**: A non-template function may be a friend to all template class instantiations.
- **Many-to-one**: All instantiations of a template function may be friends to a regular non-template class.
- **One-to-one**: A template function instantiated with one set of template arguments may be a friend to one template class instantiated with the same set of template arguments. This is also the relationship between a regular non-template class and a regular non-template friend function.
- **Many-to-many**: All instantiations of a template function may be a friend to all instantiations of the template class.

The following example demonstrates these relationships:

```c
class B{
    template<class V> friend int j();
}

template<class S> g();

template<class T> class A {
    friend int e();
    friend int f(T);
    friend int g<T>();
    template<class U> friend int h();
};
```

- Function `e()` has a one-to-many relationship with class `A`. Function `e()` is a friend to all instantiations of class `A`.
- Function `f()` has a one-to-one relationship with class `A`. The compiler will give you a warning for this kind of declaration similar to the following:
  
  The friend function declaration "f" will cause an error when the enclosing template class is instantiated with arguments that declare a friend function that does not match an existing definition. The function declares only one function because it is not a template but the function type depends on one or more template parameters.

- Function `g()` has a one-to-one relationship with class `A`. Function `g()` is a function template. It must be declared before here or else the compiler will not recognize `g<T>` as a template name. For each instantiation of `A` there is one matching instantiation of `g()`. For example, `g<int>` is a friend of `A<int>`.
- Function `h()` has a many-to-many relationship with class `A`. Function `h()` is a function template. For all instantiations of `A` all instantiations of `h()` are friends.
- Function `j()` has a many-to-one relationship with class `B`.

These relationships also apply to friend classes.

Related reference

"Friends" on page 270

Function templates

A function template defines how a group of functions can be generated.

A non-template function is not related to a function template, even though the non-template function may have the same name and parameter profile as those of a specialization generated from a template. A non-template function is never considered to be a specialization of a function template.
The following example implements the quicksort algorithm with a function template named quicksort:

```cpp
#include <iostream>
#include <cstdlib>
using namespace std;

template<class T> void quicksort(T a[], const int& leftarg, const int& rightarg)
{
    if (leftarg < rightarg) {
        T pivotvalue = a[leftarg];
        int left = leftarg - 1;
        int right = rightarg + 1;

        for(;;) {
            while (a[--right] > pivotvalue);
            while (a[++left] < pivotvalue);
            if (left >= right) break;

            T temp = a[right];
            a[right] = a[left];
            a[left] = temp;
        }

        int pivot = right;
        quicksort(a, leftarg, pivot);
        quicksort(a, pivot + 1, rightarg);
    }
}

int main(void) {
    int sortme[10];
    for (int i = 0; i < 10; i++) {
        sortme[i] = rand();
        cout << sortme[i] << " ";
    }
    cout << endl;
    quicksort<int>(sortme, 0, 10 - 1);
    for (int i = 0; i < 10; i++) cout << sortme[i] << " ";
    cout << endl;
    return 0;
}
```

The above example will have output similar to the following:

```
16838 5758 10113 17515 31051 5627 23010 7419 16212 4086
4086 5627 5758 7419 10113 16212 16838 17515 23010 31051
```

This quicksort algorithm will sort an array of type T (whose relational and assignment operators have been defined). The template function takes one template argument and three function arguments:

- the type of the array to be sorted, T
- the name of the array to be sorted, a
- the lower bound of the array, leftarg
- the upper bound of the array, rightarg

In the above example, you can also call the quicksort() template function with the following statement:

```cpp
quicksort(sortme, 0, 10 - 1);
```
When you call a template function, you may omit any template argument that the compiler can determine or deduce by the usage and context of that template function call.

The compiler tries to deduce a template argument by comparing the type of the corresponding template parameter with the type of the argument used in the function call. The two types that the compiler compares (the template parameter and the argument used in the function call) must be of a certain structure in order for template argument deduction to work. The following lists these type structures:

\[
\begin{align*}
T & \\
\text{const } T & \\
\text{volatile } T & \\
T & \\
T[10] & \\
A<T> & \\
C(*)(T) & \\
T(*)(U) & \\
T C::* & \\
C T::* & \\
T U::* & \\
T (C::*)) & \\
C (T::*)) & \\
D (C::*)) & \\
T (C::*)) & \\
T (U::*)) & \\
T (U::*)) & \\
E[10][i] & \\
B<i> & \\
TT<T> & \\
TT<T> & \\
TT<T> & \\
\end{align*}
\]

- \( T, U, \) and \( V \) represent a template type argument
- \( 10 \) represents any integer constant
- \( i \) represents a template non-type argument

\[\text{C++0x}\]

**Template argument deduction**

You may omit any template argument if the compiler can deduce it by the usage and context of the template function call. In this case, the compiler deduces that `sortme` is an array of type `int`.

\[\text{C++0x}\]

Template parameter packs can be a kind of template parameter for function templates, and function parameter packs can be a kind of function parameter for function templates. For more information, see "Variadic templates (C++0x)" on page 356.

You can use trailing return types for function templates, include those that have the following kinds of return types:
- Return types depending on the types of the function arguments
- Complicated return types

For more information, see "Trailing return type (C++0x)" on page 202.
• \([i]\) represents an array bound of a reference or pointer type, or a non-major array bound of a normal array.
• \(TT\) represents a template template argument
• \([T]\), \([U]\), and \([V]\) represents an argument list that has at least one template type argument
• \(()\) represents an argument list that has no template arguments
• \(<T>\) represents a template argument list that has at least one template type argument
• \(<i>\) represents a template argument list that has at least one template non-type argument
• \(<C>\) represents a template argument list that has no template arguments dependent on a template parameter

The following example demonstrates the use of each of these type structures. The example declares a template function using each of the above structures as an argument. These functions are then called (without template arguments) in order of declaration. The example outputs the same list of type structures:

```
#include <iostream>
using namespace std;

// Template class arguments
template<class T> class A{};
template<int i> class B{};

class C {
    public:
        int x;
};

class D {
    public:
        C y;
        int z;
};

// Template function arguments
template<class T> void f (T) { cout << "T" << endl; };
template<class T> void f1(const T) { cout << "const T" << endl; };
template<class T> void f2(volatile T) { cout << "volatile T" << endl; };
template<class T> void g (T*) { cout << "T*" << endl; };
template<class T> void g (T&) { cout << "T&" << endl; };
template<class T> void g1(T[10]) { cout << "T[10]" << endl; };
template<class T> void h1(A<T>) { cout << "A<T>" << endl; };

void test_1() {
    A<char> a;
    C c;

    f(c); f1(c); f2(c);
    g(c); g(&c); g1(&c);
    h1(a);
}

template<class T> void j(C(*)(T)) { cout << "C(*) (T)" << endl; };
template<class T> void j(T(*)()) { cout << "T(*) ()" << endl; };
template<class T, class U> void j(T(*)(U)) { cout << "T(*) (U)" << endl; };

void test_2() {
    C (*c_pfunct1)(int);
    C (*c_pfunct2)(void);
    int (*c_pfunct3)(int);
    j(c_pfunct1);
    j(c_pfunct2);
    j(c_pfunct3);
}

template<class T> void k(T C::*{ C::*} { cout << "T C::*" << endl; };
```

Chapter 15. Templates (C++ only) 339
template<class T, class U> void k(T U::* ) { cout << "T U::*" << endl; }

void test_3() {
  k(&C::x);
  k(&D::y);
  k(&D::z);
}

template<class T> void m(T (C::*)())
  { cout << "T (C::*)()" << endl; }

template<class T> void m(C (T::*)())
  { cout << "C (T::* )" << endl; }

template<class T, class U> void m(D (C::*)(T))
  { cout << "D (C::* )()" << endl; }

void test_4() {
  int (C::*f_membp1)(void);
  C (D::*f_membp2)(void);
  D (C::*f_membp3)(int);
  m(f_membp1);
  m(f_membp2);
  m(f_membp3);

  C (D::*f_membp4)(int);
  int (C::*f_membp5)(int);
  int (D::*f_membp6)(void);
  m(f_membp4);
  m(f_membp5);
  m(f_membp6);

  int (D::*f_membp7)(int);
  m(f_membp7);
}

template<int i> void n(C[10][i]) { cout << "E[10][i]" << endl; }

template<int i> void n(B<i>) { cout << "B<i>" << endl; }

void test_5() {
  C array[10][20];
  n(array);
  B<20> b;
  n(b);
}

template<template<class> class TT, class T> void p1(TT<T>)]
  { cout << "TT<T>" << endl; }

template<template<int> class TT, int i> void p2(TT<i>)
  { cout << "TT<i>" << endl; }

template<template<class> class TT> void p3(TT<C>)
  { cout << "TT<C>" << endl; }

void test_6() {
  A<char> a;
  B<20> b;
  A<C> c;
  p1(a);
  p2(b);
  p3(c);
int main() { test_1(); test_2(); test_3(); test_4(); test_5(); test_6(); }

Deducing type template arguments

The compiler can deduce template arguments from a type composed of several of the listed type structures. The following example demonstrates template argument deduction for a type composed of several type structures:

```cpp
template<class T> class Y {}; 

template<class T, int i> class X {
public:
  Y<T> f(char[20][i]) { return x; }
  Y<T> x;
};

template<template<class> class T, class U, class V, class W, int i>
void g(T<U>(V::*)(W[20][i])){};

int main()
{
  Y<int> (X<int, 20>::*p)(char[20][20]) = &X<int, 20>::f;
  g(p);
}
```

The type `Y<int> (X<int, 20>::*p)(char[20][20])T<U>(V::*)(W[20][i])` is based on the type structure `T(U::*)(V)`:
- `T` is `Y<int>`
- `U` is `X<int, 20>`
- `V` is `char[20][20]`

If you qualify a type with the class to which that type belongs, and that class (a `nested name specifier`) depends on a template parameter, the compiler will not deduce a template argument for that parameter. If a type contains a template argument that cannot be deduced for this reason, all template arguments in that type will not be deduced. The following example demonstrates this:

```cpp
template<class T, class U, class V>
void h(typename Y<T>::template Z<U>, Y<T>, Y<V>) { };

int main()
{
  Y<int>::Z<char> a;
  Y<int> b;
  Y<float> c;

  h<int, char, float>(a, b, c);
  h<int, char>(a, b, c);
  // h<int>(a, b, c);
}
```

The compiler will not deduce the template arguments `T` and `U` in `typename Y<T>::template Z<U>` (but it will deduce the `T` in `Y<T>`). The compiler would not allow the template function call `h<int>(a, b, c)` because `U` is not deduced by the compiler.

The compiler can deduce a function template argument from a pointer to function or pointer to member function argument given several overloaded function names. However, none of the overloaded functions may be function templates, nor can more than one overloaded function match the required type. The following example demonstrates this:

```cpp
template<class T> void f(void(*)(T,int)) { };

template<class T> void g1(T, int) { };
```
void g2(int, int) { };
void g2(char, int) { };

void g3(int, int, int) { };
void g3(float, int) { };

int main() {
    // f(&g1);
    // f(&g2);
    f(&g3);
}

The compiler would not allow the call f(&g1) because g1() is a function template. The compiler would not allow the call f(&g2) because both functions named g2() match the type required by f().

The compiler cannot deduce a template argument from the type of a default argument. The following example demonstrates this:

template<class T> void f(T = 2, T=3) {};

int main() {
    f(6);
    // f();
    f<int>();
}

The compiler allows the call f(6) because the compiler deduces the template argument (int) by the value of the function call's argument. The compiler would not allow the call f() because the compiler cannot deduce template argument from the default arguments of f().

The compiler cannot deduce a template type argument from the type of a non-type template argument. For example, the compiler will not allow the following:

template<class T, T i> void f(int[20][i]) { };

int main () {
    int b[20][20];
    int c[20];
    f(b);
    // g(c);
    h(c);
}

The compiler would not allow the call g(c); the compiler cannot deduce template argument i.

Deducing non-type template arguments

The compiler cannot deduce the value of a major array bound unless the bound refers to a reference or pointer type. Major array bounds are not part of function parameter types. The following code demonstrates this:

template<int i> void f(int a[10][i]) { };
template<int i> void g(int a[i]) { };
template<int i> void h(int (&a)[i]) { };

int main () {
    int b[10][20];
    int c[10];
    f(b);
    // g(c);
    h(c);
}

The compiler would not allow the call g(c); the compiler cannot deduce template argument i.
The compiler cannot deduce the value of a non-type template argument used in an expression in the template function’s parameter list. The following example demonstrates this:

template<int i> class X { }; 

template<int i> void f(X<i - 1>) { }; 

int main() {
    X<0> a;
    f<1>(a);
    // f(a);
}

To call function f() with object a, the function must accept an argument of type X<0>. However, the compiler cannot deduce that the template argument i must be equal to 1 in order for the function template argument type X<i - 1> to be equivalent to X<0>. Therefore the compiler would not allow the function call f(a).

If you want the compiler to deduce a non-type template argument, the type of the parameter must match exactly the type of value used in the function call. For example, the compiler will not allow the following:

template<int i> class A { }; 

template<short d> void f(A<d>) { }; 

int main() {
    A<1> a;
    f(a); 
}

The compiler will not convert int to short when the example calls f().

However, deduced array bounds may be of any integral type.

C++0x

Template argument deduction also applies to the variadic templates feature. For more information, see "Variadic templates (C++0x)" on page 356.

Overloading function templates

You may overload a function template either by a non-template function or by another function template.

If you call the name of an overloaded function template, the compiler will try to deduce its template arguments and check its explicitly declared template arguments. If successful, it will instantiate a function template specialization, then add this specialization to the set of candidate functions used in overload resolution. The compiler proceeds with overload resolution, choosing the most appropriate function from the set of candidate functions. Non-template functions take precedence over template functions. The following example describes this:

```
#include <iostream>
using namespace std;

template<class T> void f(T x, T y) { cout << "Template" << endl; }

void f(int w, int z) { cout << "Non-template" << endl; }

int main() {
    f(1, 2);
    f('a', 'b');
    f(1, 'b');
}
```
The following is the output of the above example:

Non-template
Template
Non-template

The function call \( f(1, 2) \) could match the argument types of both the template function and the non-template function. The non-template function is called because a non-template function takes precedence in overload resolution.

The function call \( f(\text{'a'}, \text{'b'}) \) can only match the argument types of the template function. The template function is called.

Argument deduction fails for the function call \( f(1, \text{'b'}) \); the compiler does not generate any template function specialization and overload resolution does not take place. The non-template function resolves this function call after using the standard conversion from char to int for the function argument \( \text{'b'} \).

Related reference
"Overload resolution" on page 241

Partial ordering of function templates

A function template specialization might be ambiguous because template argument deduction might associate the specialization with more than one of the overloaded definitions. The compiler will then choose the definition that is the most specialized. This process of selecting a function template definition is called partial ordering.

A template \( X \) is more specialized than a template \( Y \) if every argument list that matches the one specified by \( X \) also matches the one specified by \( Y \), but not the other way around. The following example demonstrates partial ordering:

```cpp
template<class T> void f(T) { }
template<class T> void f(T*) { }
template<class T> void f(const T*) { }
template<class T> void g(T) { }
template<class T> void g(T&) { }
template<class T> void h(T) { }
template<class T> void h(T, ...) { }

int main() {
    const int *p;
    f(p);
    int q;
    // g(q);
    // h(q);
}
```

The declaration \( \text{template<class T> void f(const T*)} \) is more specialized than \( \text{template<class T> void f(T*)} \). Therefore, the function call \( f(p) \) calls \( \text{template<class T> void f(const T*)} \). However, neither \( \text{void g(T)} \) nor \( \text{void g(T&)} \) is more specialized than the other. Therefore, the function call \( g(q) \) would be ambiguous.

Ellipses do not affect partial ordering. Therefore, the function call \( h(q) \) would also be ambiguous.

The compiler uses partial ordering in the following cases:

- Calling a function template specialization that requires overload resolution.
- Taking the address of a function template specialization.
When a friend function declaration, an explicit instantiation, or explicit specialization refers to a function template specialization.

Determining the appropriate deallocation function that is also a function template for a given placement operator new.

Template instantiation

The act of creating a new definition of a function, class, or member of a class from a template declaration and one or more template arguments is called template instantiation. The definition created from a template instantiation to handle a specific set of template arguments is called a specialization.

Template instantiation has two forms: explicit instantiation and implicit instantiation.

Related reference
“Template specialization” on page 349

Explicit instantiation

You can explicitly tell the compiler when it should generate a definition from a template. This is called explicit instantiation. Explicit instantiation includes two forms: explicit instantiation declaration and explicit instantiation definition.

C++0x
Note: C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

Explicit instantiation declaration

The explicit instantiation declarations feature is introduced in the C++0x standard. With this feature, you can suppress the implicit instantiation of a template specialization or its members. The extern keyword is used to indicate explicit instantiation declaration. The usage of extern here is different from that of a storage class specifier.

Explicit instantiation declaration syntax

You can provide an explicit instantiation declaration for a template specialization if an explicit instantiation definition of the template exists in other translation units or later in the same file. If one translation unit contains the explicit instantiation definition, other translation units can use the specialization without having the specialization instantiated multiple times. The following example demonstrates this concept:

```
//sample1.h:
template<typename T, T val>
union A{
  T foo();
};
extern template union A<int, 55>;
```
template<class T, T val>
T A<T,val>::foo(void)
{
    return val;
}

//sampleA.C
#include "sample1.h"

template union A<int,55>;

//sampleB.C:
#include "sample1.h"

int main(void)
{
    return A<int, 55>().foo();
}

sampleB.C uses the explicit instantiation definition of A<int, 55>().foo() in sampleA.C.

If an explicit instantiation declaration of a function or class is declared, but there is no corresponding explicit instantiation definition anywhere in the program, the compiler issues an error message. See the following example:

// sample2.C
template <typename T, T val>
struct A{
    virtual T foo();
    virtual T bar();
}

extern template int A<int,55>::foo();

template <class T, T val>
T A<T,val>::foo(void){
    return val;
}

template <class T, T val>
T A<T,val>::bar(void){
    return val;
}

int main(void){
    return A<int,55>().bar();
}

When you use explicit instantiation declaration, pay attention to the following restrictions:
- You can name a static class member in an explicit instantiation declaration, but you cannot name a static function because a static function cannot be accessed by name in other translation units.
- Explicit instantiation declarations have no effect on inline functions. An inline function is still implicitly instantiated even if an explicit instantiation declaration of the inline function is present, but no out-of-line copy of the inline function is generated in this case.
- The explicit instantiation declaration of a class is not equivalent to the explicit instantiation declaration of each of its members.

Explicit instantiation definition

An explicit instantiation definition is an instantiation of a template specialization or a its members.
Explicit instantiation definition syntax

Here is an example of explicit instantiation definition:

```cpp
template<class T> class Array { void mf();};
template class Array<char>; /* explicit instantiation definition */
template void Array<int>::mf(); /* explicit instantiation definition */

template<T> void sort(Array<T>& v) {}
template void sort(Array<char>&); /* explicit instantiation definition */
	namespace N {
    template<class T> void f(T&) {} } // The explicit instantiation definition is in namespace N.

template void N::f<int>(int&);

int* p = 0;
template<class T> T g(T = &p); // explicit instantiation definition *
template char g(char); /* explicit instantiation definition */

namespace N {
    template<class T> void f(T&) {} // The explicit instantiation definition is in namespace N.
}

template void N::f<int>(int&);

int* p = 0;
template<class T> T g(T = &p); // explicit instantiation definition *
template char g(char); /* explicit instantiation definition */

namespace N {
    template<class T> void f(T&) {} // The explicit instantiation definition is in namespace N.
}

An explicit instantiation definition of a template is in the same namespace where you define the template.

Access checking rules do not apply to the arguments in the explicit instantiation definitions. Template arguments in an explicit instantiation definition can be private types or objects. In this example, you can use the explicit instantiation definition template int X<int>::v(int) even though the member function is declared to be private.

The compiler does not use default arguments when you explicitly instantiate a template. In this example, you can use the explicit instantiation definition template char g(char) even though the default argument is an address of the type int.

C++0x

Explicit instantiation and inline namespace definitions

Inline namespace definitions are namespace definitions with an initial `inline` keyword. Members of an inline namespace can be explicitly instantiated or specialized as if they were also members of the enclosing namespace. For more information, see "Inline namespace definitions (C++0x)" on page 227
Implicit instantiation

Unless a template specialization has been explicitly instantiated or explicitly specialized, the compiler will generate a specialization for the template only when it needs the definition. This is called implicit instantiation.

The compiler does not need to generate the specialization for nonclass, noninline entities when an explicit instantiation declaration is present.

If the compiler must instantiate a class template specialization and the template is declared, you must also define the template.

For example, if you declare a pointer to a class, the definition of that class is not needed and the class will not be implicitly instantiated. The following example demonstrates when the compiler instantiates a template class:

```cpp
template<class T> class X {
public:
 X* p;
 void f();
 void g();
1};
X<int>* q;
X<int> r;
X<float>* s;
r.f();
s->g();
```

The compiler requires the instantiation of the following classes and functions:
- `X<int>` when the object `r` is declared
- `X<int>::f()` at the member function call `r.f()`
- `X<float>` and `X<float>::g()` at the class member access function call `s->g()`

Therefore, the functions `X<T>::f()` and `X<T>::g()` must be defined in order for the above example to compile. (The compiler will use the default constructor of class `X` when it creates object `r`.) The compiler does not require the instantiation of the following definitions:
- `X<int>` when the pointer `p` is declared
- `X<int>` when the pointer `q` is declared
- `X<float>` when the pointer `s` is declared

The compiler will implicitly instantiate a class template specialization if it is involved in pointer conversion or pointer to member conversion. The following example demonstrates this:

```cpp
template<class T> class B {}; 
template<class T> class D : public B<T> {}; 
void g(D<double>* p, D<int>* q) 
{ 
 B<double>* r = p;
 delete q;
}
```

Related reference

“Extensions for C++0x compatibility” on page 495
The assignment `B<double>* r = p` converts `p` of type `D<double>*` to a type of `B<double>*`; the compiler must instantiate `D<double>`. The compiler must instantiate `D<int>` when it tries to delete `q`.

If the compiler implicitly instantiates a class template that contains static members, those static members are not implicitly instantiated. The compiler will instantiate a static member only when the compiler needs the static member’s definition. Every instantiated class template specialization has its own copy of static members. The following example demonstrates this:

```cpp
template<class T> class X { 
public:
   static T v;
};

template<class T> T X<T>::v = 0;

X<char*> a;
X<float> b;
X<float> c;
```

Object `a` has a static member variable `v` of type `char*`. Object `b` has a static variable `v` of type `float`. Objects `b` and `c` share the single static data member `v`.

An implicitly instantiated template is in the same namespace where you defined the template.

If a function template or a member function template specialization is involved with overload resolution, the compiler implicitly instantiates a declaration of the specialization.

### Template specialization

The act of creating a new definition of a function, class, or member of a class from a template declaration and one or more template arguments is called template instantiation. The definition created from a template instantiation is called a specialization. A primary template is the template that is being specialized.

**Related reference**

"Template instantiation" on page 345

### Explicit specialization

When you instantiate a template with a given set of template arguments the compiler generates a new definition based on those template arguments. You can override this behavior of definition generation. You can instead specify the definition the compiler uses for a given set of template arguments. This is called explicit specialization. You can explicitly specialize any of the following:

- Function or class template
- Member function of a class template
- Static data member of a class template
- Member class of a class template
- Member function template of a class template
- Member class template of a class template

**Explicit specialization declaration syntax**

```
<template-declaration-name>
<template-argument-list>
```

Chapter 15. Templates (C++ only)  349
The `template<>` prefix indicates that the following template declaration takes no template parameters. The `declaration_name` is the name of a previously declared template. Note that you can forward-declare an explicit specialization so the `declaration_body` is optional, at least until the specialization is referenced.

The following example demonstrates explicit specialization:

```cpp
using namespace std;

template<class T = float, int i = 5> class A
{
    public:
        A();
        int value;
};

template<> class A<> { public: A(); };

template<class T, int i> class A<T, i> { public: A(); };

template<class T, int i> A<T, i>::A() : value(i) {
    cout << "Primary template, "
        << "non-type argument is " << value << endl;
}

A<>::A() {
    cout << "Explicit specialization "
        << "default arguments" << endl;
}

A<double, 10>::A() {
    cout << "Explicit specialization "
        << "<double, 10>" << endl;
}

int main() {
    A<int,6> x;
    A<> y;
    A<double, 10> z;
}
```

The following is the output of the above example:

```
Primary template non-type argument is: 6
Explicit specialization default arguments
Explicit specialization <double, 10>
```

This example declared two explicit specializations for the `primary template` (the template which is being specialized) class `A`. Object `x` uses the constructor of the `primary template`. Object `y` uses the explicit specialization `A<>::A()`. Object `z` uses the explicit specialization `A<double, 10>::A()`.

**Definition and declaration of explicit specializations**

The definition of an explicitly specialized class is unrelated to the definition of the primary template. You do not have to define the primary template in order to define the specialization (nor do you have to define the specialization in order to define the primary template). For example, the compiler will allow the following:

```cpp
template<class T> class A;

template<> class A<int>;

template<> class A<int> { /* ... */ };
```

The primary template is not defined, but the explicit specialization is.

You can use the name of an explicit specialization that has been declared but not defined the same way as an incompletely defined class. The following example demonstrates this:
template<class T> class X {}

-template<> class X<char>;

X<char>* p;
X<int> i;
// X<char> j;

The compiler does not allow the declaration X<char> j because the explicit specialization of X<char> is not defined.

**Explicit specialization and scope**

A declaration of a primary template must be in scope at the *point of declaration* of the explicit specialization. In other words, an explicit specialization declaration must appear after the declaration of the primary template. For example, the compiler will not allow the following:

```
template<> class A<int>;
template<class T> class A;
```

An explicit specialization is in the same namespace as the definition of the primary template.

**Class members of explicit specializations**

A member of an explicitly specialized class is not implicitly instantiated from the member declaration of the primary template. You have to explicitly define members of a class template specialization. You define members of an explicitly specialized template class as you would normal classes, without the `template<>` prefix. In addition, you can define the members of an explicit specialization inline; no special template syntax is used in this case. The following example demonstrates a class template specialization:

```
template<class T> class A {
    public:
        void f(T);
};

template<> class A<int> {
    public:
        int g(int);
};

int A<int>::g(int arg) { return 0; }

int main() {
    A<int> a;
    a.g(1234);
}
```

The explicit specialization A<int> contains the member function g(), which the primary template does not.

If you explicitly specialize a template, a member template, or the member of a class template, then you must declare this specialization before that specialization is implicitly instantiated. For example, the compiler will not allow the following code:

```
template<class T> class A {}

void f() { A<int> x; }
template<> class A<int> { }

int main() { f(); }
```

The compiler will not allow the explicit specialization template<> class A<int> { }; because function f() uses this specialization (in the construction of x) before the specialization.
Explicit specialization of function templates

In a function template specialization, a template argument is optional if the compiler can deduce it from the type of the function arguments. The following example demonstrates this:

```cpp
template<class T> class X {}; 
template<class T> void f(X<T>); 
template<> void f(X<int>); 
```

The explicit specialization `template<> void f(X<int>)` is equivalent to `template<> void f<int>(X<int>)`.

You cannot specify default function arguments in a declaration or a definition for any of the following:

- Explicit specialization of a function template
- Explicit specialization of a member function template

For example, the compiler will not allow the following code:

```cpp
template<class T> void f(T a) { }; 
template<> void f<int>(inta = 5) {} ; 
template<class T> class X { 
    void f(T a) {} 
}; 
template<> void X<int>::f(int a = 10) {} ; 
```

Explicit specialization of members of class templates

Each instantiated class template specialization has its own copy of any static members. You may explicitly specialize static members. The following example demonstrates this:

```cpp
template<class T> class X { 
    public: 
        static T v; 
        static void f(T); 
}; 

template<class T> T X<T>::v = 0; 
template<class T> void X<T>::f(T arg) { v = arg; } 

template<> char* X<char*>::v = "Hello"; 
template<> void X<float>::f(float arg) { v = arg * 2; } 
```

```cpp
int main() { 
    X<char*> a, b; 
    X<float> c; 
    c.f(10); 
}
```

This code explicitly specializes the initialization of static data member `X::v` to point to the string "Hello" for the template argument `char*`. The function `X::f()` is explicitly specialized for the template argument `float`. The static data member `v` in objects `a` and `b` point to the same string, "Hello". The value of `c.v` is equal to 20 after the call function call `c.f(10)`.

You can nest member templates within many enclosing class templates. If you explicitly specialize a template nested within several enclosing class templates, you must prefix the declaration with `template<>` for every enclosing class template you specialize. You may leave some enclosing class templates unspecialized, however you cannot explicitly specialize a class template unless its enclosing class templates are also explicitly specialized. The following example demonstrates explicit specialization of nested member templates:

```cpp
#include <iostream> 
using namespace std; 

template<class T> class X { 
```

352  z/OS V1R13.0 XL C/C++ Language Reference
```cpp
public:
  template<class U> class Y {
  public:
    template<class V> void f(U, V);
    void g(U);
  }
};

template<class T> template<class U> template<class V>
void X<T>::Y<U>::f(U, V) { cout << "Template 1" << endl; }

template<class T> template<class U>
void X<T>::Y<U>::g(U) { cout << "Template 2" << endl; }

template<> template<> template<class V>
void X<int>::Y<int>::f(int, V) { cout << "Template 4" << endl; }

// template<> template<class U> template<class V>
// void X<char>::Y<U>::f(U, V) { cout << "Template 6" << endl; }

template<> template<> template<class V>
void X<int>::Y<int>::f<int>(int, int) { cout << "Template 5" << endl; }

interface template<> template<class U> template<class V>
void X<char>::Y<U>::g(U) { cout << "Template 3" << endl; }

interface template<> template<class V>
void X<int>::Y<int>::g(float) { cout << "Template 7" << endl; }

int main() {
  X<int>::Y<int> a;
  X<char>::Y<char> b;
  a.f(1, 2);
  a.f(3, 'x');
  a.g(3);
  b.f('x', 'y');
  b.g('z');
}
```

The following is the output of the above program:

Template 5
Template 4
Template 3
Template 1
Template 2

- The compiler would not allow the template specialization definition that would output "Template 6"
  because it is attempting to specialize a member (function f()) without specialization of its containing
class (Y).
- The compiler would not allow the template specialization definition that would output "Template 7"
  because the enclosing class of class Y (which is class X) is not explicitly specialized.

A friend declaration cannot declare an explicit specialization.

---

**Explicit specialization and inline namespace definitions**

Inline namespace definitions are namespace definitions with an initial `inline` keyword. Members of an
inline namespace can be explicitly instantiated or specialized as if they were also members of the
enclosing namespace. For more information, see "Inline namespace definitions (C++0x)" on page 227
Partial specialization

When you instantiate a class template, the compiler creates a definition based on the template arguments you have passed. Alternatively, if all those template arguments match those of an explicit specialization, the compiler uses the definition defined by the explicit specialization.

A partial specialization is a generalization of explicit specialization. An explicit specialization only has a template argument list. A partial specialization has both a template argument list and a template parameter list. The compiler uses the partial specialization if its template argument list matches a subset of the template arguments of a template instantiation. The compiler will then generate a new definition from the partial specialization with the rest of the unmatched template arguments of the template instantiation.

You cannot partially specialize function templates.

Partial specialization syntax

```
template<template_parameter_list> declaration_name<template_argument_list>
```

The declaration_name is a name of a previously declared template. Note that you can forward-declare a partial specialization so that the declaration_body is optional.

The following demonstrates the use of partial specializations:

```c++
#include <iostream>
using namespace std;

template<class T, class U, int I> struct X
{ void f() { cout << "Primary template" << endl; } };

template<class T, int I> struct X<T, T*, I>
{ void f() { cout << "Partial specialization 1" << endl; } };

template<class T, class U, int I> struct X<T*, U, I>
{ void f() { cout << "Partial specialization 2" << endl; } };

template<class T> struct X<int, T*, 10>
{ void f() { cout << "Partial specialization 3" << endl; } };

template<class T, class U, int I> struct X<T, U*, I>
{ void f() { cout << "Partial specialization 4" << endl; } };

int main()
{ X<int, int, 10> a;
  X<int, int*, 5> b;
  X<int*, float, 10> c;
  X<int, char*, 10> d;
}
X<float, int*, 10> e;
// X<int, int*, 10> f;
a.f(); b.f(); c.f(); d.f(); e.f();
}

The following is the output of the above example:

Primary template
Partial specialization 1
Partial specialization 2
Partial specialization 3
Partial specialization 4

The compiler would not allow the declaration X<int, int*, 10> f because it can match template struct
X<T, T*, I>, template struct X<int, T*, 10>, or template struct X<T, U*, I>, and none of these
declarations are a better match than the others.

Each class template partial specialization is a separate template. You must provide definitions for each
member of a class template partial specialization.

**Template parameter and argument lists of partial specializations**

Primary templates do not have template argument lists; this list is implied in the template parameter list.

Template parameters specified in a primary template but not used in a partial specialization are omitted
from the template parameter list of the partial specialization. The order of a partial specialization's
argument list is the same as the order of the primary template's implied argument list.

In a template argument list of a partial template parameter, you cannot have an expression that involves
non-type arguments unless that expression is only an identifier. In the following example, the compiler will
not allow the first partial specialization, but will allow the second one:

```cpp
template<int I, int J> class X{};
// Invalid partial specialization
template<int I> class X<4*I, 4+3>{};
// Valid partial specialization
template<int I> class X<4*I, 4+3>{};
```

The type of a non-type template argument cannot depend on a template parameter of a partial
specialization. The compiler will not allow the following partial specialization:

```cpp
template<class T, T i> class X{};
// Invalid partial specialization
template<class T> class X<T, 25>{};
```

A partial specialization's template argument list cannot be the same as the list implied by the primary
template.

You cannot have default values in the template parameter list of a partial specialization.

**Matching of class template partial specializations**

The compiler determines whether to use the primary template or one of its partial specializations by
matching the template arguments of the class template specialization with the template argument lists of
the primary template and the partial specializations:

- If the compiler finds only one specialization, then the compiler generates a definition from that
  specialization.
• If the compiler finds more than one specialization, then the compiler tries to determine which of the
specializations is the most specialized. A template X is more specialized than a template Y if every
argument list that matches the one specified by X also matches the one specified by Y, but not the other
way around. If the compiler cannot find the most specialized specialization, then the use of the class
template is ambiguous; the compiler will not allow the program.
• If the compiler does not find any matches, then the compiler generates a definition from the primary
template.

**C++0x**

Partial specialization also applies to the variadic templates feature. For more information, see “Variadic
templates (C++0x)”.

### Variadic templates (C++0x)

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and
has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's
interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM
makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language
extension should not be relied on as a stable programming interface.

Before C++0x, templates had a fixed number of parameters that must be specified in the declaration of the
templates. Templates could not directly express a class or function template that had a variable number of
parameters. To partially alleviate this problem in the existing C++ programs, you could use overloaded
function templates that had a different number of parameters or extra defaulted template parameters.

With the variadic templates feature, you can define class or function templates that have any number
(including zero) of parameters. To achieve this goal, this feature introduces a kind of parameter called a
parameter pack to represent a list of zero or more parameters for templates.

The variadic template feature also introduces pack expansion to indicate that a parameter pack is
expanded.

Two existing techniques, template argument deduction and partial specialization, can also apply to
templates that have parameter packs in their parameter lists.

#### Parameter packs

A parameter pack can be a type of parameter for templates. Unlike previous parameters, which can only
bind to a single argument, a parameter pack can pack multiple parameters into a single parameter by
placing an ellipsis to the left of the parameter name.

In the template definition, a parameter pack is treated as a single parameter. In the template instantiation,
a parameter pack is expanded and the correct number of the parameters is created.

According to the context where a parameter pack is used, the parameter pack can be either a template
parameter pack or a function parameter pack.

**Template parameter packs**

A template parameter pack is a template parameter that represents any number (including zero) of
template parameters. Syntactically, a template parameter pack is a template parameter specified
with an ellipsis. Consider the following example.
template<class...A> struct container{};
template<class...B> void func();

In this example, A and B are template parameter packs.

According to the type of the parameters contained in a template parameter pack, there are three kinds of template parameter packs:
- Type parameter packs
- Non-type parameter packs
- Template template parameter packs

A type parameter pack represents zero or more type template parameters. Similarly, a non-type parameter pack represents zero or more non-type template parameters.

**Note:** Template template parameter packs are not supported in z/OS XL C/C++ V1R13.

The following example shows a type parameter pack:
```cpp
template<class...T> class X{};
X<> a; // the parameter list is empty
X<int> b; // the parameter list has one item
X<int, char, float> c; // the parameter list has three items
```

In this example, the type parameter pack T is expanded into a list of zero or more type template parameters.

The following example shows a non-type parameter pack:
```cpp
template<bool...A> class X{};
X<> a; // the parameter list is empty
X<true> b; // the parameter list has one item
X<true, false, true> c; // the parameter list has three items
```

In this example, the non-type parameter pack A is expanded into a list of zero or more non-type template parameters.

In a context where template arguments can be deduced (function templates, class template partial specializations, and class template explicit instantiations), a template parameter pack does not need to be the last template parameter of a template, and you can declare more than one template parameter pack in the template parameter list. However, if template arguments cannot be deduced, a template parameter pack must be the last template parameter in the template parameter list. Consider the following example:
```cpp
template<class...A, class...B> struct container{};
```

In this example, the compiler issues an error message because the class template container has two template parameter packs A and B.

In a context where template arguments cannot be deduced, a template parameter pack must be placed after other normal template parameters in the template parameter list. Consider the following example:
```cpp
template<class...A,class B> struct container{};
```

In this example, the compiler issues an error message because the template parameter pack A is not the last template parameter in the template parameter list of the class template container.

Default arguments cannot be used for a template parameter pack. Consider the following example:
```cpp
template<typename...T=int> struct foo1{};
```
In this example, the compiler issues an error message because the template parameter pack T is given a
default argument int.

**Function parameter packs**

A *function parameter pack* is a function parameter that represents zero or more function
parameters. Syntactically, a function parameter pack is a function parameter specified with an
ellipsis.

In the definition of a function template, a function parameter pack uses a template parameter pack in the
function parameters. The template parameter pack is expanded by the function parameter pack. Consider
the following example:

```cpp
template<class...A> void func(A...args)
```

In this example, A is a template parameter pack, and args is a function parameter pack. You can call the
function with any number (including zero) of arguments:

```cpp
func(); // void func();
func(1); // void func(int);
func(1,2,3,4,5); // void func(int,int,int,int,int);
func(1,'x', aWidget); // void func(int,char,widget);
```

A function template can have at most one function parameter pack in its parameter list, and the function
parameter pack must be the last function parameter, as shown in the following example:

```cpp
// Okay. Function parameter pack arg2 is in the last position
template<class...A, class B> void func(B arg1, A...arg2);
// Error. Function parameter pack arg1 is not in the last position
template<class...A, class B> void func(A...arg1,B arg2);
```

In this example, the template arguments can be deduced in the function template func, so the template
parameter pack A does not need to be the last template parameter. For the same reason, a function
template in this context can have more than one template parameter pack in its parameter list. Consider
the following example:

```cpp
template<class...A> struct container{};
template<class...B, class...C> void func(container<B,C>...args);
```

In this example, the function template func has two template parameter packs B and C in its parameter list.

**Pack expansion**

A *pack expansion* is an expression that contains one or more parameter packs followed by an ellipsis to
indicate that the parameter packs are expanded. Consider the following example:

```cpp
template<class...T> void func(T...a){{
    func(b...);
}
```

In this example, T... and U... are the corresponding pack expansions of the template parameter packs T
and U, and b... is the pack expansion of the function parameter pack b.

A pack expansion can be used in the following contexts:

- Expression list
- Initializer list
- Base specifier list
- Member initializer list
- Template argument list
Exception specification list

Expression list

Example:

```c
#include <cstdio>
#include <cassert>

template<class...A> void func1(A...arg){
    assert(false);
}

template<class...A> int func(A...args){
    int size = sizeof...(A);
    switch(size){
    case 0: func1(99,99,99,99,99,99);
        break;
    case 1: func1(99,99,99,99,99,99);
        break;
    case 2: func1(99,99,99,99,99,99);
        break;
    case 3: func1(99,99,99,99,99,99);
        break;
    case 4: func1(99,99,99,99,99,99);
        break;
    case 5: func1(99,99,99,99,99,99);
        break;
    default:
        func1(0,0,0,0,0,0);
    }
    return size;
}

int main(void){
    func();
    func(1);
    func(1,2);
    func(1,2,3);
    func(1,2,3,4);
    func(1,2,3,4,5);
    func(1,2,3,4,5,6);
    func(1,2,3,4,5,6,7);
    return 0;
}
```

The output of this example:

call with (99,99,1,99,99,99)
call with (99,99,1,2,99,99)
call with (1,2,3,99,99,99)
call with (99,1,2,3,4,99)
call with (99,1,2,3,4,5)
call with (1,2,3,4,5,6)
call with (0,0,0,0,0,0)

In this example, the switch statement shows the different positions of the pack expansion args... within the expression lists of the function func1. The output shows each call of the function func1 to indicate the expansion.
Initializer list

Example:
#include <iostream>
using namespace std;

void printarray(int arg[], int length)
{
    for(int n=0; n<length; n++)
    {
        printf("%d ",arg[n]);
    }
    printf("\n");
}

template<class...A> void func(A...args)
{
    const int size = sizeof...(args) +5;
    printf("size %d\n", size);
    int res[sizeof...(args)+5]={99,98,args...,97,96,95};
    printarray(res,size);
}

int main(void)
{
    func();
    func(1);
    func(1,2);
    func(1,2,3);
    func(1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20);
    return 0;
}

The output of this example:
size 5
99 98 97 96 95
size 6
99 98 1 97 96 95
size 7
99 98 1 2 97 96 95
size 8
99 98 1 2 3 97 96 95
size 25
99 98 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20 97 96 95

In this example, the pack expansion args... is in the initializer list of the array res.

Base specifier list

Example:
#include <iostream>
using namespace std;

struct a1{};
struct a2{};
struct a3{};
struct a4{};
template<class X> struct baseC{
    baseC() {printf("baseC primary ctor\n");}
};
template<> struct baseC<a1>{
    baseC() {printf("baseC a1 ctor\n");}
};
template<> struct baseC<a2>{
    baseC() {printf("baseC a2 ctor\n");}
};
template<> struct baseC<a3>{
    baseC() {printf("baseC a3 ctor\n");}
};
template<> struct baseC<a4>{
    baseC() {printf("baseC a4 ctor\n");}
};
template<class...A> struct container : public baseC<A>...{
    container(){
        printf("container ctor\n");
    }
};

int main(void){
    container<a1,a2,a3,a4> test;
    return 0;
}

The output of this example:

baseC a1 ctor
baseC a2 ctor
baseC a3 ctor
baseC a4 ctor
container ctor

In this example, the pack expansion baseC<A>... is in the base specifier list of the class template container. The pack expansion is expanded into four base classes baseC<a1>, baseC<a2>, baseC<a3>, and baseC<a4>. The output shows that all the four base class templates are initialized before the instantiation of the class template container.

Member initializer list

Example:

#include <iostream>
using namespace std;

struct a1{};
struct a2{};
struct a3{};
struct a4{};
template<class X> struct baseC{
    baseC(int a) {printf("baseC primary ctor: %d\n", a);}  
};
template<> struct baseC<a1>{
    baseC(int a) {printf("baseC a1 ctor: %d\n", a);}  
};
template<> struct baseC<a2>{
    baseC(int a) {printf("baseC a2 ctor: %d\n", a);}  
};
template<> struct baseC<a3>{
    baseC(int a) {printf("baseC a3 ctor: %d\n", a);}  
};
template<> struct baseC<a4>{
    baseC(int a) {printf("baseC a4 ctor: %d\n", a);}  
};
template<class...A> struct container : public baseC<A>...{
    container(): baseC<A>(12)...{
        printf("container ctor\n");
    }
};
int main(void){
    container<a1,a2,a3,a4> test;
    return 0;
}

The output of this example:
baseC a1 ctor:12
baseC a2 ctor:12
baseC a3 ctor:12
baseC a4 ctor:12
container ctor

In this example, the pack expansion baseC<A>(12)… is in the member initializer list of the class template container. The constructor initializer list is expanded to include the call for each base class baseC<a1>(12), baseC<a2>(12), baseC<a3>(12), and baseC<a4>(12).

Template argument list

Example:
#include <iostream>
using namespace std;

template<int val> struct value{
    operator int(){return val;}
};
template<typename...I> struct container{
    container(){
        int array[sizeof...(I)]={I()...};
        printf("container<");
        for(int count = 0; count<sizeof...(I); count++){
            if(count>0){
                printf(",");
            }
            printf("%d", array[count]);
        }
        printf(">
");
    }
};
template<class A, class B, class...C> void func(A arg1, B arg2, C...arg3){
    container<A,B,C,...> t1; // container<99,98,3,4,5,6>
    container<C,...,A,B> t2; // container<3,4,5,6,99,98>
    container<A,C,...,B> t3; // container<99,3,4,5,6,98>
}

int main(void){
    value<99> v99;
    value<98> v98;
    value<3> v3;
    value<4> v4;
    value<5> v5;
    value<6> v6;
    func(v99,v98,v3,v4,v5,v6);
    return 0;
}

The output of this example:
container<99,98,3,4,5,6>
container<3,4,5,6,99,98>
container<99,3,4,5,6,98>
In this example, the pack expansion \( \ldots \) is expanded in the context of template argument list for the class template container.

Exception specification list

Example:

```cpp
struct a1{};
struct a2{};
struct a3{};
struct a4{};
struct a5{};
struct stuff{};

template<class...X> void func(int arg) throw(X...){
    a1 t1;
    a2 t2;
    a3 t3;
    a4 t4;
    a5 t5;
    stuff st;
    switch(arg){
        case 1:
            throw t1;
            break;
        case 2:
            throw t2;
            break;
        case 3:
            throw t3;
            break;
        case 4:
            throw t4;
            break;
        case 5:
            throw t5;
            break;
        default:
            throw st;
            break;
    }
}
```

```cpp
int main(void){
    try{
        // if the throw specification is correctly expanded, none of
        // these calls should trigger an exception that is not expected
        func<a1,a2,a3,a4,a5,stuff>(1);
        func<a1,a2,a3,a4,a5,stuff>(2);
        func<a1,a2,a3,a4,a5,stuff>(3);
        func<a1,a2,a3,a4,a5,stuff>(4);
        func<a1,a2,a3,a4,a5,stuff>(5);
        func<a1,a2,a3,a4,a5,stuff>(99);
    }
    catch(...){
        return 0;
    }
    return 1;
}
```

In this example, the pack expansion \( \ldots \) is expanded in the context of exception specification list for the function template `func`.
If a parameter pack is declared, it must be expanded by a pack expansion. An appearance of a name of a parameter pack that is not expanded is incorrect. Consider the following example:

```
template<class...A> struct container;
template<class...B> struct container<B>();
```

In this example, the compiler issues an error message because the template parameter pack `B` is not expanded.

Pack expansion cannot match a parameter that is not a parameter pack. Consider the following example:

```
template<class X> struct container{};
template<class A, class...B>
// Error, parameter A is not a parameter pack
void func1(container<A>...args){};
template<class A, class...B>
// Error, 1 is not a parameter pack
void func2(1...){};
```

If more than one parameter pack is referenced in a pack expansion, each expansion must have the same number of arguments expanded from these parameter packs. Consider the following example:

```
struct a1{}; struct a2{}; struct a3{}; struct a4{}; struct a5{}
template<class...X> struct baseC{};
template<class...A> struct container{};
template<class...A, class...B, class...C>
struct container<baseC<A,B,C...>...>:public baseC<A,B...,C>{};
int main(void)
{
    container<baseC<a1,a4,a5,a5,a5>, baseC<a2,a3,a5,a5, a5>, baseC<a3,a2,a5,a5,a5>,baseC<a4,a1,a5,a5,a5> > test;
    return 0;
}
```

In this example, the template parameter packs `A`, `B`, and `C` are referenced in the same pack expansion `baseC<A,B,C...>...`. The compiler issues an error message to indicate that the lengths of these three template parameter packs are mismatched when expanding them during the template instantiation of the class template `container`.

Partial specialization

Partial specialization is a fundamental part of the variadic templates feature. A basic partial specialization can be used to access the individual arguments of a parameter pack. The following example shows how to use partial specialization for variadic templates:

```
// primary template
template<class...A> struct container;

// partial specialization
template<class B, class...C> struct container<B,C...>{};
```

When the class template `container` is instantiated with a list of arguments, the partial specialization is matched in all cases where there are one or more arguments. In that case, the template parameter `B` holds the first parameter, and the pack expansion `C...` contains the rest of the argument list. In the case of an empty list, the partial specialization is not matched, so the instantiation matches the primary template.

A pack expansion must be the last argument in the argument list for a partial specialization. Consider the following example:
template<class...A> struct container;

// partial specialization
template<class B, class...C> struct container<C...,B>{};

In this example, the compiler issues an error message because the pack expansion C... is not the last argument in the argument list for the partial specialization.

A partial specialization can have more than one template parameter pack in its parameter list. Consider the following example:

```cpp
template<typename T1, typename T2> struct foo{};
template<typename...T> struct bar{};

// partial specialization
template<typename...T1,typename...T2> struct bar<foo<T1,T2>...>{};
```

In this example, the partial specialization has two template parameter packs T1 and T2 in its parameter list.

To access the arguments of a parameter pack, you can use partial specialization to access one member of the parameter pack in the first step, and recursively instantiate the remainder of the argument list to get all the elements, as shown in the following example:

```cpp
#include<iostream>
using namespace std;

struct a1{}; struct a2{}; struct a3{}; struct a4{}; struct a5{};
struct a6{}; struct a7{}; struct a8{}; struct a9{}; struct a10{};

template<typename X1, typename X2> struct foo{foo();};
template<typename X3, typename X4> foo<X3,X4>::foo(){cout<<"primary foo"<<endl;};
template<>
struct foo<a1,a2>{foo(){cout<<"ctor foo<a1,a2>"<<endl;}};
template<>
struct foo<a3,a4>{foo(){cout<<"ctor foo<a3,a4>"<<endl;}};
template<>
struct foo<a5,a6>{foo(){cout<<"ctor foo<a5,a6>"<<endl;}};
template<>
struct foo<a7,a8>{foo(){cout<<"ctor foo<a7,a8>"<<endl;}};
template<>
struct foo<a9,a10>{foo(){cout<<"ctor foo<a9,a10>"<<endl;}};

template<typename...T> struct bar<foo<T1,T2>...>{
    foo<T1,T2> data;
    bar<foo<T1,T2>...>data1;
};

template<>
struct bar<foo<a9,a10>> {bar(){cout<<"ctor bar<foo<a9,a10>>"<<endl;}};

int main()
    {bar<foo<a9,a10> > {bar(){cout<<"ctor bar<foo<a9,a10>>"<<endl;}};
        return 0;
    }
```

The output of the example:

```
ctor foo<a1,a2>
ctor foo<a3,a4>
ctor foo<a5,a6>
ctor foo<a7,a8>
ctor bar<foo<a9,a10>
```

**Template argument deduction**

Parameter packs can be deduced by template argument deduction in the same way as other normal template parameters. The following example shows how template argument deduction expands packs from a function call:
template<class...A> void func(A...args){}

int main(void){
    func(1,2,3,4,5,6);
    return 0;
}

In this example, the function argument list is (1,2,3,4,5,6). Each function argument is deduced to the type int, so the template parameter pack A is deduced to the following list of types: (int,int,int,int,int,int). With all the expansions, the function template func is instantiated as void func(int,int,int,int,int,int), which is the template function with the expanded function parameter pack.

In this example, if you change the function call statement func(1,2,3,4,5,6) to func(), template argument deduction deduces that the template parameter pack A is empty:

template<class...A> void func(A...args){}

int main(void){
    func();
    return 0;
}

Template argument deduction can expand packs from a template instantiation, as shown in the following example:

#include <cstdio>

template<int...A> struct container{
    void display(){printf("YIKES\n");}
};

template<int B, int...C> struct container<B,C...>{
    void display(){
        printf("spec %d\n",B);
        container<C...>test;
        test.display();
    }
};

template<int C> struct container<C>{
    void display(){printf("spec %d\n",C);}
};

int main(void)
{
    printf("start\n\n");
    container<1,2,3,4,5,6,7,8,9,10> test;
    test.display();
    return 0;
}

The output of this example:

start

Spec 1
Spec 2
Spec 3
Spec 4
Spec 5
Spec 6
In this example, the partial specialization of the class template `container` is `template<int B, int...C> struct container<B,C...>`. The partial specialization is matched when the class template is instantiated to `container<1,2,3,4,5,6,7,8,9,10>`. Template argument deduction deduces the template parameter pack `C` and the parameter `B` from the argument list of the partial specialization. Template argument deduction then deduces the parameter `B` to be 1, the pack expansion `C...` to a list: (2,3,4,5,6,7,8,9,10), and the template parameter pack `C` to the following list of types: (int,int,int,int,int,int,int,int,int).

If you change the statement `container<1,2,3,4,5,6,7,8,9,10> test` to `container<1> test`, template argument deduction deduces that the template parameter pack `C` is empty.

Template argument deduction can expand packs after the explicit template arguments are found. Consider the following example:

```cpp
#include <cassert>

template<class...A> int func(A...arg){
  return sizeof...(arg);
}

int main(void){
  assert(func<int>(1,2,3,4,5) == 5);
  return 0;
}
```

In this example, the template parameter pack `A` is deduced to a list of types: (int,int,int,int,int) using the explicit argument list and the arguments in the function call.

**Name binding and dependent names**

_Name binding_ is the process of finding the declaration for each name that is explicitly or implicitly used in a template. The compiler might bind a name in the definition of a template, or it might bind a name at the instantiation of a template.

A _dependent name_ is a name that depends on the type or the value of a template parameter. For example:

```cpp
template<class T> class U : A<T>
{
  typename T::B x;
  void f(A<T>& y)
  {
    *y++;
  }
};
```
The dependent names in this example are the base class `A<T>`, the type name `T::B`, and the variable `y`.

The compiler binds dependent names when a template is instantiated. The compiler binds non-dependent names when a template is defined. Consider the following example:

```cpp
#include <iostream>
using namespace std;

void f(double) { cout << "Function f(double)" << endl; }

template <class A> struct container { // point of definition of container
  void member1() {
    // This call is not template dependent,
    // because it does not make any use of a template parameter.
    // The name is resolved at the point of definition, so f(int) is not visible.
    f(1);
  }
  void member2(A arg);
};

void f(int) { cout << "Function f(int)" << endl; }
void h(double) { cout << "Function h(double)" << endl; }

template <class A> void container<A>::member2(A arg) {
  // This call is template dependent, so qualified name lookup only finds
  // names visible at the point of instantiation.
  ::h(arg);
}

template struct container<int>; // point of instantiation of container<int>

void h(int) { cout << "Function h(int)" << endl; }

int main(void) {
  container<int> test;
  test.member1();
  test.member2(10);
  return 0;
}
```

The output of this example:

```
Function f(double)
Function h(double)
```

The point of definition of a template is located immediately before its definition. In this example, the point of definition of the template `container` is located immediately before the keyword `template`. Because the function call `f(1)` does not depend on a template parameter, the compiler considers names declared before the definition of the template `container`. Therefore, the function call `f(1)` calls `f(double)`. Although `f(int)` is a better match, it is not in scope at the point of definition of `container`.

The point of instantiation of a template is located immediately before the declaration that encloses its use. In this example, the point of instantiation of `container<int>` is the location of the explicit instantiation. Because the qualified function call `::h(arg)` depends on the template argument `arg`, the compiler considers names declared before the instantiation of `container<int>`. Therefore, the function call `h(arg)` calls `h(double)`. It does not consider `h(int)`, because this function is not in scope at the point of instantiation of `container<int>`.

Point of instantiation binding implies the following:

- A template parameter cannot depend on any local name or class member.
- An unqualified name in a template cannot depend on a local name or class member.
The decltype feature can interact with template dependent names. If the operand expression in the decltype(expression) type specifier is dependent on template parameters, the compiler cannot determine the validity of expression before the template instantiation, as shown in the following example:

```
template <class T, class U> int h(T t, U u, decltype(t+u) v);
```

In this example, the compiler issues an error message if the operand t+u is invalid after the instantiation of the function template h.

For more information, see "The decltype(expression) type specifier (C++0x)" on page 69.

### The typename keyword

Use the keyword typename if you have a qualified name that refers to a type and depends on a template parameter. Only use the keyword typename in template declarations and definitions. Consider the following example:

```
template<class T> class A
{ 
 T::x(y);
 typedef char C;
 A::C d;
 }
```

The statement T::x(y) is ambiguous. It could be a call to function x() with a nonlocal argument y, or it could be a declaration of variable y with type T::x. C++ compiler interprets this statement as a function call. In order for the compiler to interpret this statement as a declaration, you must add the keyword typename to the beginning of T::x(y). The statement A::C d; is ill-formed. The class A also refers to A<T> and thus depends on a template parameter. You must add the keyword typename to the beginning of this declaration:

```
typename A::C d;
```

You can also use the keyword typename in place of the keyword class in the template parameter declarations.

"Template parameters" on page 326

---

### The template keyword as qualifier

Use the keyword template as a qualifier to distinguish member templates from other entities. The following example illustrates when you must use template as a qualifier:

```
class A
{ 
 public:
    template<class T> T function_m() { }; 
};
```
template<class U> void function_n(U argument)
{
    char object_x = argument.function_m<char>(); // ill-formed
}

In this example, the definition of the variable object_x is ill-formed. The compiler assumes that the symbol < is a less-than operator. In order for the compiler to recognize the template function call, you must add the template qualifier:
char object_x = argument.template function_m<char>();

If the name of a member template specialization appears after a .-, ->, or :: operator, and that name has explicitly qualified template parameters, prefix the member template name with the keyword template. The following example demonstrates this use of the keyword template:
#include <iostream>
using namespace std;

class X {
    public:
        template <int j> struct S {
            void h() {
                cout << "member template's member function: " << j << endl;
            }
        };
        template <int i> void f() {
            cout << "Primary: " << i << endl;
        }
    };
    template<> void X::f<20>() {
        cout << "Specialized, non-type argument = 20" << endl;
    }
    template<class T> void g(T* p) {
        p->template f<100>();
        p->template f<20>();
        typename T::template S<40> s; // use of scope operator on a member template
         s.h();
    }
    int main()
    {
        X temp;
        g(&temp);
    }

    The following is the output of this example:
    Primary: 100
    Specialized, non-type argument = 20
    member template's member function: 40

    If you do not use the keyword template in these cases, the compiler will interpret the < as a less-than operator. For example, the following line of code is ill-formed:
p->f<100>();

    The compiler interprets f as a non-template member, and the < as a less-than operator.
Chapter 16. Exception handling (C++ only)

Exception handling is a mechanism that separates code that detects and handles exceptional circumstances from the rest of your program. Note that an exceptional circumstance is not necessarily an error.

When a function detects an exceptional situation, you represent this with an object. This object is called an exception object. In order to deal with the exceptional situation you throw the exception. This passes control, as well as the exception, to a designated block of code in a direct or indirect caller of the function that threw the exception. This block of code is called a handler. In a handler, you specify the types of exceptions that it may process. The C++ run time, together with the generated code, will pass control to the first appropriate handler that is able to process the exception thrown. When this happens, an exception is caught. A handler may rethrow an exception so it can be caught by another handler.

The exception handling mechanism is made up of the following elements:
- try blocks
- catch blocks
- throw expressions
- "Exception specifications" on page 383

try blocks

You use a try block to indicate which areas in your program that might throw exceptions you want to handle immediately. You use a function try block to indicate that you want to detect exceptions in the entire body of a function.

try block syntax

```cpp
try \{ statements \} handler
```

Function try block syntax

```cpp
try [ : member_initializer_list ] function_body handler
```

The following is an example of a function try block with a member initializer, a function try block and a try block:

```cpp
#include <iostream>
using namespace std;

class E {
public:
    const char* error;
    E(const char* arg) : error(arg) {} };

class A {
public:
    int i;
    // A function try block with a member initializer
    // initialzer
```
A() try : i(0) {
    throw E("Exception thrown in A()" seating
    );
    catch (E& e) {
        cout << e.error << endl;
    }
}

// A function try block
void f() try {
    throw E("Exception thrown in f() seating
    ");
    catch (E& e) {
        cout << e.error << endl;
    }
}

void g() {
    throw E("Exception thrown in g() seating
    ");
}

int main() {
    f();
    // A try block
    try {
        g();
        catch (E& e) {
            cout << e.error << endl;
        }
        try {
            A x;
        }
        catch(...) {
    }
    
    The following is the output of the above example:
    Exception thrown in f()
    Exception thrown in g()
    Exception thrown in A()

The constructor of class A has a function try block with a member initializer. Function f() has a function try block. The main() function contains a try block.

Related reference
"Initialization of base classes and members" on page 308

Nested try blocks

When try blocks are nested and a throw occurs in a function called by an inner try block, control is transferred outward through the nested try blocks until the first catch block is found whose argument matches the argument of the throw expression.

For example:
try {
    func1();
    try {
        func2();
    }
    catch (spec_err) { /* ... */ }
}
In the above example, if spec_err is thrown within the inner try block (in this case, from func2()), the exception is caught by the inner catch block, and, assuming this catch block does not transfer control, func3() is called. If spec_err is thrown after the inner try block (for instance, by func3()), it is not caught and the function terminate() is called. If the exception thrown from func2() in the inner try block is type_err, the program skips out of both try blocks to the second catch block without invoking func3(), because no appropriate catch block exists following the inner try block.

You can also nest a try block within a catch block.

**catch blocks**

**catch block syntax**

```
catch (exception_declaration){ statements }
```

You can declare a handler to catch many types of exceptions. The allowable objects that a function can catch are declared in the parentheses following the `catch` keyword (the `exception_declaration`). You can catch objects of the fundamental types, base and derived class objects, references, and pointers to all of these types. You can also catch `const` and `volatile` types. The `exception_declaration` cannot be an incomplete type, or a reference or pointer to an incomplete type other than one of the following:

- `void`
- `const void*`
- `volatile void*`
- `const volatile void*`

You cannot define a type in an `exception_declaration`.

You can also use the `catch(...)` form of the handler to catch all thrown exceptions that have not been caught by a previous catch block. The ellipsis in the catch argument indicates that any exception thrown can be handled by this handler.

If an exception is caught by a `catch(...)` block, there is no direct way to access the object thrown. Information about an exception caught by `catch(...)` is very limited.

You can declare an optional variable name if you want to access the thrown object in the catch block.

A catch block can only catch accessible objects. The object caught must have an accessible copy constructor.

**Related reference**

- "Type qualifiers" on page 74
- "Member access" on page 268

**Function try block handlers**

The scope and lifetime of the parameters of a function or constructor extend into the handlers of a function try block. The following example demonstrates this:

```cpp
void f(int &x) try {
    throw 10;
}
catch (const int &i) {
    func3();
}
catch (type_err) { /* ... */ }
// if no throw is issued, control resumes here.
```

You can also nest a try block within a catch block.

**catch blocks**

**catch block syntax**

```
catch (exception_declaration){ statements }
```

You can declare a handler to catch many types of exceptions. The allowable objects that a function can catch are declared in the parentheses following the `catch` keyword (the `exception_declaration`). You can catch objects of the fundamental types, base and derived class objects, references, and pointers to all of these types. You can also catch `const` and `volatile` types. The `exception_declaration` cannot be an incomplete type, or a reference or pointer to an incomplete type other than one of the following:

- `void`
- `const void*`
- `volatile void*`
- `const volatile void*`

You cannot define a type in an `exception_declaration`.

You can also use the `catch(...)` form of the handler to catch all thrown exceptions that have not been caught by a previous catch block. The ellipsis in the catch argument indicates that any exception thrown can be handled by this handler.

If an exception is caught by a `catch(...)` block, there is no direct way to access the object thrown. Information about an exception caught by `catch(...)` is very limited.

You can declare an optional variable name if you want to access the thrown object in the catch block.

A catch block can only catch accessible objects. The object caught must have an accessible copy constructor.

**Related reference**

- "Type qualifiers" on page 74
- "Member access" on page 268

**Function try block handlers**

The scope and lifetime of the parameters of a function or constructor extend into the handlers of a function try block. The following example demonstrates this:

```cpp
void f(int &x) try {
    throw 10;
}
catch (const int &i) {
    func3();
}
catch (type_err) { /* ... */ }
// if no throw is issued, control resumes here.
```
The value of v after f() is called is 10.

A function try block on main() does not catch exceptions thrown in destructors of objects with static storage duration, or constructors of namespace scope objects.

The following example throws an exception from a destructor of a static object. This example is intended to show that the exception in ~B() is caught by the function try block of main(), but that the exception in ~A() is not caught because ~A() is executed after main() has completed.

```c++
#include <iostream>
using namespace std;

class E {
    public:
        const char* error;
        E(const char* arg) : error(arg) { }
    }

class A {
    public:
        A() { throw E("Exception in ~A()"); }
    }

class B {
    public:
        B() { throw E("Exception in ~B()"); }
    }

    int main() try {
        cout << "In main" << endl;
        static A cow;
        B bull;
    }
    catch (E& e) {
        cout << e.error << endl;
    }
```

The following is the output of the above example:

```
In main
Exception in ~B()
```

The run time will not catch the exception thrown when object cow is destroyed at the end of the program.

The following example throws an exception from a constructor of a namespace scope object:

```c++
#include <iostream>
using namespace std;

class E {
    public:
        const char* error;
        E(const char* arg) : error(arg) { }
    }

namespace N {
    class C {
        public:
            C() {
```
cout << "In C()" << endl;
    throw E("Exception in C()");
};

C calf;
);

int main() try {
    cout << "In main" << endl;
} catch (E& e) {
    cout << e.error << endl;
}

The following is the output of the above example:
In C()

The compiler will not catch the exception thrown when object calf is created.

In a function try block's handler, you cannot have a jump into the body of a constructor or destructor.

A return statement cannot appear in a function try block's handler of a constructor.

When the function try block's handler of an object's constructor or destructor is entered, fully constructed base classes and members of that object are destroyed. The following example demonstrates this:
#include <iostream>
using namespace std;

class E {
    public:
        const char* error;
        E(const char* arg) : error(arg) { }
};
class B {
    public:
        B() { }
        "B() { cout << "B() called" << endl; }
};
class D : public B {
    public:
        D();
        "D() { cout << "D() called" << endl; }
};

D::D() try : B() {
    throw E("Exception in D()");
} catch(E& e) {
    cout << "Handler of function try block of D(): " << e.error << endl;
};

int main() {
    try {
        D val;
    } catch(...) { }
}

The following is the output of the above example:
~B() called
Handler of function try block of D(): Exception in D()

When the function try block's handler of D() is entered, the run time first calls the destructor of the base class of D, which is B. The destructor of D is not called because val is not fully constructed.

The run time will rethrow an exception at the end of a function try block's handler of a constructor or destructor. All other functions will return once they have reached the end of their function try block's handler. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

class E {
public:
   const char* error;
   E(const char* arg) : error(arg) { };
};
class A {
public:
   A() try { throw E("Exception in A()"); }  
   catch(E& e) { cout << \"Handler in A(): \" << e.error << endl; }
};

int f() try {
   throw E("Exception in f()");
   return 0;
} catch(E& e) {
   cout << \"Handler in f(): \" << e.error << endl;
   return 1;
}

int main() {
   int i = 0;
   try { A cow; }  
   catch(E& e) {
      cout << \"Handler in main(): \" << e.error << endl;
   }
   try { i = f(); } catch(E& e) {
      cout << \"Another handler in main(): \" << e.error << endl;
   }
   cout << \"Returned value of f(): \" << i << endl;
}
```

The following is the output of the above example:

Handler in A(): Exception in A()
Handler in main(): Exception in A()
Handler in f(): Exception in f()
Returned value of f(): 1

> C++0x

If the delegating process exists and an exception occurs in the body of a target constructor, the exception can be caught by an appropriate handler in the try block of the delegating constructor. The following example demonstrates this:

```cpp
#include <cstdio>
using std::printf;

int global_argc;
```
struct A{
    int _x;
    A();
    A(int);
};
A::A(int x):_x((printf("In A::A(int) initializer for A::_x.\n"),x)){
    printf("In A::A(int) constructor body.\n");
    if(global_argc % 2 !=0){
        printf("Will throw.\n");
        throw 0;
    }
    printf("Will not throw.\n");
}
A::A() try:A((printf("In A::A() initializer for delegating to A::A(int).\n"),42)){
    printf("In A::A() function-try-block body.\n");
} catch(...){
    printf("In catch(...) handler for A::A() function-try-block.\n");
}
int main(int argc, char **argv){
    printf("In main().\n");
    global_argc = argc;
    try{
        A a;
        printf("Back in main().\n");
    } catch(...){
        printf("In catch(...) handler for try-block in main().\n");
    }
    return 0;
}

The example can produce different output depending on how many arguments are passed on the
invocation of the resulting program. With an even number of arguments, the exception is thrown. The
output is:
In main().
In A::A() initializer for delegating to A::A(int).
In A::A(int) initializer for A::_x.
In A::A(int) constructor body.
Will throw.
In catch(...) handler for A::A() function-try-block.
In catch(...) handler for try-block in main().

With an odd number of arguments, there is no exception thrown. The output is:
In main().
In A::A() initializer for delegating to A::A(int).
In A::A(int) initializer for A::_x.
In A::A(int) constructor body.
Will not throw.
In A::A() function-try-block body.
Back in main().

For more information, see "Delegating constructors (C++0x)" on page 306
Arguments of catch blocks

If you specify a class type for the argument of a catch block (the exception_declaration), the compiler uses a copy constructor to initialize that argument. If that argument does not have a name, the compiler initializes a temporary object and destroys it when the handler exits.

The ISO C++ specifications do not require the compiler to construct temporary objects in cases where they are redundant. The compiler takes advantage of this rule to create more efficient, optimized code. Take this into consideration when debugging your programs, especially for memory problems.

Matching between exceptions thrown and caught

An argument in the catch argument of a handler matches an argument in the assignment_expression of the throw expression (throw argument) if any of the following conditions is met:

- The catch argument type matches the type of the thrown object.
- The catch argument is a public base class of the thrown class object.
- The catch specifies a pointer type, and the thrown object is a pointer type that can be converted to the pointer type of the catch argument by standard pointer conversion.

Note: If the type of the thrown object is const or volatile, the catch argument must also be a const or volatile for a match to occur. However, a const, volatile, or reference type catch argument can match a nonconstant, nonvolatile, or nonreference object type. A nonreference catch argument type matches a reference to an object of the same type.

“Type qualifiers” on page 74
“References (C++ only)” on page 92

Order of catching

If the compiler encounters an exception in a try block, it will try each handler in order of appearance.

If a catch block for objects of a base class precedes a catch block for objects of a class derived from that base class, the compiler issues a warning and continues to compile the program despite the unreachable code in the derived class handler.

A catch block of the form catch(...) must be the last catch block following a try block or an error occurs. This placement ensures that the catch(...) block does not prevent more specific catch blocks from catching exceptions intended for them.

If the run time cannot find a matching handler in the current scope, the run time will continue to find a matching handler in a dynamically surrounding try block. The following example demonstrates this:

```cpp
#include <iostream>
using namespace std;

class E {
public:
```
const char* error;
E(const char* arg) : error(arg) {);
};

class F : public E {
public:
F(const char* arg) : E(arg) {);
};

void f() {
try {
    cout << "In try block of f()" << endl;
    throw E("Class E exception");
}
catch (F& e) {
    cout << "In handler of f()";
    cout << e.error << endl;
}];
}

int main() {
try {
    cout << "In main" << endl;
    f();
}
catch (E& e) {
    cout << "In handler of main: ";
    cout << e.error << endl;
}];
cout << "Resume execution in main" << endl;
}

The following is the output of the above example:
In main
In try block of f()
In handler of main: Class E exception
Resume execution in main

In function f(), the run time could not find a handler to handle the exception of type E thrown. The run time finds a matching handler in a dynamically surrounding try block: the try block in the main() function.

If the run time cannot find a matching handler in the program, it calls the terminate() function.

Related reference
“try blocks” on page 371

throw expressions

You use a throw expression to indicate that your program has encountered an exception.

throw expression syntax

```
throw assignment_expression
```

The type of assignment_expression cannot be an incomplete type, or a pointer to an incomplete type other than one of the following:

- void*
- const void*
- volatile void*
- const volatile void*
The *assignment_expression* is treated the same way as a function argument in a call or the operand of a return statement.

If the *assignment_expression* is a class object, the copy constructor and destructor of that object must be accessible. For example, you cannot throw a class object that has its copy constructor declared as private.

**Related reference**

*Incomplete types*

## Rethrowing an exception

If a catch block cannot handle the particular exception it has caught, you can rethrow the exception. The rethrow expression (`throw` without *assignment_expression*) causes the originally thrown object to be rethrown.

Because the exception has already been caught at the scope in which the rethrow expression occurs, it is rethrown out to the next dynamically enclosing try block. Therefore, it cannot be handled by catch blocks at the scope in which the rethrow expression occurred. Any catch blocks for the dynamically enclosing try block have an opportunity to catch the exception.

The following example demonstrates rethrowing an exception:

```cpp
#include <iostream>
using namespace std;

struct E {
    const char* message;
    E() : message("Class E") {}  
};

struct E1 : E {
    const char* message;
    E1() : message("Class E1") {}  
};

struct E2 : E {
    const char* message;
    E2() : message("Class E2") {}  
};

void f() {
    try {
        cout << "In try block of f()" << endl;
        cout << "Throwing exception of type E1" << endl;
        E1 myException;
        throw myException;
    }
    catch (E2& e) {
        cout << "In handler of f(), catch (E2& e)" << endl;
        cout << "Exception: " << e.message << endl;
        throw;
    }
    catch (E1& e) {
        cout << "In handler of f(), catch (E1& e)" << endl;
        cout << "Exception: " << e.message << endl;
        throw;
    }
    catch (E& e) {
        cout << "In handler of f(), catch (E& e)" << endl;
        cout << "Exception: " << e.message << endl;
        throw;
    }
}
```

380 z/OS V1R13.0 XL C/C++ Language Reference
int main() {
    try {
        cout << "In try block of main()" << endl;
        f();
    }
    catch (E2& e) {
        cout << "In handler of main(), catch (E2& e)" << endl;
        cout << "Exception: " << e.message << endl;
    }
    catch (...) {
        cout << "In handler of main(), catch (...)" << endl;
    }
}

The following is the output of the above example:
In try block of main()
In try block of f()
Throwing exception of type E1
In handler of f(), catch (E1 &e)
Exception: Class E1
In handler of main(), catch (...)

The try block in the main() function calls function f(). The try block in function f() throws an object of type E1 named myException. The handler catch (E1 &e) catches myException. The handler then rethrows myException with the statement throw to the next dynamically enclosing try block: the try block in the main() function. The handler catch(...) catches myException.

Stack unwinding

When an exception is thrown and control passes from a try block to a handler, the C++ run time calls destructors for all automatic objects constructed since the beginning of the try block. This process is called stack unwinding. The automatic objects are destroyed in reverse order of their construction. (Automatic objects are local objects that have been declared auto or register, or not declared static or extern. An automatic object x is deleted whenever the program exits the block in which x is declared.)

If an exception is thrown during construction of an object consisting of subobjects or array elements, destructors are only called for those subobjects or array elements successfully constructed before the exception was thrown. A destructor for a local static object will only be called if the object was successfully constructed.

If during stack unwinding a destructor throws an exception and that exception is not handled, the terminate() function is called. The following example demonstrates this:

#include <iostream>
using namespace std;

struct E {
    const char* message;
    E(const char* arg) : message(arg) { }
};

void my_terminate() {
    cout << "Call to my_terminate" << endl;
};

struct A {
    A() { cout << "In constructor of A" << endl; }
    ~A() {
        cout << "In destructor of A" << endl;
        throw E("Exception thrown in ~A()");
    }
};
struct B {
    B() { cout << "In constructor of B" << endl; }
    ~B() { cout << "In destructor of B" << endl; }
};

int main() {
    set_terminate(my_terminate);
    try {
        cout << "In try block" << endl;
        A a;
        B b;
        throw("Exception thrown in try block of main()");
    }
    catch (const char* e) {
        cout << "Exception: " << e << endl;
    }
    catch (...) {
        cout << "Some exception caught in main()" << endl;
    }
    cout << "Resume execution of main()" << endl;
}

The output of this example:
In try block
In constructor of A
In constructor of B
In destructor of B
In destructor of A
Call to my_terminate

In the try block, two automatic objects are created: a and b. The try block throws an exception of type const char*. The handler catch (const char* e) catches this exception. The C++ run time unwinds the stack, calling the destructors for a and b in reverse order of their construction. The destructor for a throws an exception. Since there is no handler in the program that can handle this exception, the C++ run time calls terminate(). (The function terminate() calls the function specified as the argument to set_terminate(). In this example, terminate() has been specified to call my_terminate().)

When the delegating constructors feature is enabled, if an exception is thrown in the body of a delegating constructor, the destructors of the objects constructed through target constructor will be invoked automatically. The destructors must be called in such a way that it calls the destructors of subobjects as appropriate. In particular, it should call the destructors for virtual base classes if the virtual base classes are created through the target constructor.

If an exception is thrown in the body of a delegating constructor, the destructor is invoked for the object created by the target constructor. If an exception escapes from a non-delegating constructor, the unwinding mechanism will call the destructors for the completely constructed subobjects. The following example demonstrates this:

```cpp
class D{
    D():D(\'a\') { printf("D::D().\n");}
    D(D(char) try; D(55){
        printf("D::D(char). Throws.\n");
        throw 0;
    }
    catch(...) {
        printf("D::D(char).Catch block.\n");
    }
}
```
The output of the example is:
D::D(int).
D::D(char). Throws.
D::~D().
D::D(char). Catch block.

In this example, an exception occurs in the delegating constructor D::D(char), so destructor D::~D() is invoked for object d.

For more information, see “Delegating constructors (C++0x)” on page 306

**Exception specifications**

C++ provides a mechanism to ensure that a given function is limited to throw only a specified list of exceptions. An exception specification at the beginning of any function acts as a guarantee to the function's caller that the function will throw only the exceptions contained in the exception specification.

For example, a function:

```cpp
void translate() throw(unknown_word,bad_grammar) { /* ... */ }
```

explicitly states that it will only throw exception objects whose types are `unknown_word` or `bad_grammar`, or any type derived from `unknown_word` or `bad_grammar`.

**Exception specification syntax**

```cpp
throw(type_id_list)
```

The `type_id_list` is a comma-separated list of types. In this list you cannot specify an incomplete type, a pointer or a reference to an incomplete type, other than a pointer to `void`, optionally qualified with `const` and/or `volatile`. You cannot define a type in an exception specification.

A function with no exception specification allows all exceptions. A function with an exception specification that has an empty `type_id_list`, `throw()`, does not allow any exceptions to be thrown.

An exception specification is not part of a function's type.

An exception specification may only appear at the end of a function declarator of a function, pointer to function, reference to function, pointer to member function declaration, or pointer to member function definition. An exception specification cannot appear in a `typedef` declaration. The following declarations demonstrate this:

```cpp
void f() throw(int);
void (*g)() throw(int);
void h(void i() throw(int));
// typedef int (*j)() throw(int); This is an error.
```

The compiler would not allow the last declaration, `typedef int (*j)() throw(int)`.
Suppose that class A is one of the types in the *type_id_list* of an exception specification of a function. That function may throw exception objects of class A, or any class publicly derived from class A. The following example demonstrates this:

class A { }
class B : public A { }
class C { }

void f(int i) throw (A) {
    switch (i) {
    case 0: throw A();
    case 1: throw B();
    default: throw C();
    }
}

void g(int i) throw (A*) {
    A* a = new A();
    B* b = new B();
    C* c = new C();
    switch (i) {
    case 0: throw a;
    case 1: throw b;
    default: throw c;
    }
}

Function f() can throw objects of types A or B. If the function tries to throw an object of type C, the compiler will call *unexpected()* because type C has not been specified in the function's exception specification, nor does it derive publicly from A. Similarly, function g() cannot throw pointers to objects of type C; the function may throw pointers of type A or pointers of objects that derive publicly from A.

A function that overrides a virtual function can only throw exceptions specified by the virtual function. The following example demonstrates this:

class A {
    public:
        virtual void f() throw (int, char);
};
class B : public A{
    public: void f() throw (int) { }
};

/* The following is not allowed. */
/*
class C : public A {
    public: void f() { }
};
class D : public A {
    public: void f() throw (int, char, double) { }
};
*/

The compiler allows B::f() because the member function may throw only exceptions of type int. The compiler would not allow C::f() because the member function may throw any kind of exception. The compiler would not allow D::f() because the member function can throw more types of exceptions (int, char, and double) than A::f().

Suppose that you assign or initialize a pointer to function named x with a function or pointer to function named y. The pointer to function x can only throw exceptions specified by the exception specifications of y. The following example demonstrates this:
void (*f)();
void (*g)();
void (*h)() throw (int);

void i() {
    f = h;
    // h = g; This is an error.
}

The compiler allows the assignment f = h because f can throw any kind of exception. The compiler would not allow the assignment h = g because h can only throw objects of type int, while g can throw any kind of exception.

Implicitly declared special member functions (default constructors, copy constructors, destructors, and copy assignment operators) have exception specifications. An implicitly declared special member function will have in its exception specification the types declared in the functions’ exception specifications that the special function invokes. If any function that a special function invokes allows all exceptions, then that special function allows all exceptions. If all the functions that a special function invokes allow no exceptions, then that special function will allow no exceptions. The following example demonstrates this:

class A {
    public:
        A() throw (int);
        A(const A&) throw (float);
        "~A() throw();
};

class B {
    public:
        B() throw (char);
        B(const A&);
        "~B() throw();
};

class C : public B, public A {};

The following special functions in the above example have been implicitly declared:

C::C() throw (int, char);
C::C(const C&); // Can throw any type of exception, including float
C::"~C() throw();

The default constructor of C can throw exceptions of type int or char. The copy constructor of C can throw any kind of exception. The destructor of C cannot throw any exceptions.

Special exception handling functions

Not all thrown errors can be caught and successfully dealt with by a catch block. In some situations, the best way to handle an exception is to terminate the program. Two special library functions are implemented in C++ to process exceptions not properly handled by catch blocks or exceptions thrown outside of a valid try block. These functions are:

• "The unexpected() function” on page 386
• "The terminate() function” on page 387
The unexpected() function

When a function with an exception specification throws an exception that is not listed in its exception specification, the C++ run time does the following:
1. The unexpected() function is called.
2. The unexpected() function calls the function pointed to by unexpected_handler. By default, unexpected_handler points to the function terminate().

You can replace the default value of unexpected_handler with the function set_unexpected().

Although unexpected() cannot return, it may throw (or rethrow) an exception. Suppose the exception specification of a function f() has been violated. If unexpected() throws an exception allowed by the exception specification of f(), then the C++ run time will search for another handler at the call of f(). The following example demonstrates this:

```cpp
#include <iostream>
#include <exception>
using namespace std;

struct E {
    const char* message;
    E(const char* arg) : message(arg) { }
};

void my_unexpected() {
    cout << "Call to my_unexpected" << endl;
    throw E("Exception thrown from my_unexpected");
}

void f() throw(E) {
    cout << "In function f(), throw const char* object" << endl;
    throw("Exception, type const char*, thrown from f()");
}

int main() {
    set_unexpected(my_unexpected);
    try {
        f();
    } catch (E& e) {
        cout << "Exception in main": " << e.message << endl;
    }
}
```

The following is the output of the above example:

```
In function f(), throw const char* object
Call to my_unexpected
Exception in main(): Exception thrown from my_unexpected
```

The main() function's try block calls function f(). Function f() throws an object of type const char*. However the exception specification of f() allows only objects of type E to be thrown. The function unexpected() is called. The function unexpected() calls my_unexpected(). The function my_unexpected() throws an object of type E. Since unexpected() throws an object allowed by the exception specification of f(), the handler in the main() function may handle the exception.

If unexpected() did not throw (or rethrow) an object allowed by the exception specification of f(), then the C++ run time does one of two things:

- If the exception specification of f() included the class std::bad_exception, unexpected() will throw an object of type std::bad_exception, and the C++ run time will search for another handler at the call of f().

386 z/OS V1R13.0 XL C/C++ Language Reference
If the exception specification of \texttt{f()} did not include the class \texttt{std::bad\_exception}, the function \texttt{terminate()} is called.

\textbf{Related reference}

“Special exception handling functions” on page 385
“The set\_unexpected() and set\_terminate() functions” on page 388

\textbf{The terminate() function}

In some cases, the exception handling mechanism fails and a call to \texttt{void terminate()} is made. This \texttt{terminate()} call occurs in any of the following situations:

\begin{itemize}
  \item The exception handling mechanism cannot find a handler for a thrown exception. The following are more specific cases of this:
    \begin{itemize}
    \item During stack unwinding, a destructor throws an exception and that exception is not handled.
    \item The expression that is thrown also throws an exception, and that exception is not handled.
    \item The constructor or destructor of a nonlocal static object throws an exception, and the exception is not handled.
    \item A function registered with \texttt{atexit()} throws an exception, and the exception is not handled. The following demonstrates this:
    \begin{itemize}
    \item A throw expression without an operand tries to rethrow an exception, and no exception is presently being handled.
    \item A function \texttt{f()} throws an exception that violates its exception specification. The \texttt{unexpected()} function then throws an exception which violates the exception specification of \texttt{f()}, and the exception specification of \texttt{f()} did not include the class \texttt{std::bad\_exception}.
    \item The default value of \texttt{unexpected\_handler} is called.
    \end{itemize}
  \end{itemize}
\end{itemize}

The following example demonstrates that if a function registered with \texttt{atexit()} throws an exception and the exception is not handled, an invocation to \texttt{void terminate()} is made.

```c
extern "C" printf(char* ...);
#include <exception>
#include <cstdlib>
using namespace std;

extern "C" void f() {
    printf("Function f()\n");
    throw "Exception thrown from f()";
}

extern "C" void g() { printf("Function g()\n"); }
extern "C" void h() { printf("Function h()\n"); }

void my_terminate() {
    printf("Call to my\_terminate\n");
    abort();
}

int main() {
    set\_terminate(my\_terminate);
    atexit(f);
    atexit(g);
    atexit(h);
    printf("In main\n");
}
```

The following is the output of the above example:
In main
Function h()
Function g()
Function f()
Call to my_terminate

To register a function with atexit(), you pass a parameter to atexit() a pointer to the function you want to register. At normal program termination, atexit() calls the functions you have registered with no arguments in reverse order. The atexit() function is in the <cstdlib> library.

The terminate() function calls the function pointed to by terminate_handler. By default, terminate_handler points to the function abort(), which exits from the program. You can replace the default value of terminate_handler with the function set_terminate().

A terminate function cannot return to its caller, either by using return or by throwing an exception.

Related reference
“The set_unexpected() and set_terminate() functions”

The set_unexpected() and set_terminate() functions

The function unexpected(), when invoked, calls the function most recently supplied as an argument to set_unexpected(). If set_unexpected() has not yet been called, unexpected() calls terminate().

The function terminate(), when invoked, calls the function most recently supplied as an argument to set_terminate(). If set_terminate() has not yet been called, terminate() calls abort(), which ends the program.

You can use set_unexpected() and set_terminate() to register functions you define to be called by unexpected() and terminate(). The functions set_unexpected() and set_terminate() are included in the standard header files. Each of these functions has as its return type and its argument type a pointer to function with a void return type and no arguments. The pointer to function you supply as the argument becomes the function called by the corresponding special function: the argument to set_unexpected() becomes the function called by unexpected(), and the argument to set_terminate() becomes the function called by terminate().

Both set_unexpected() and set_terminate() return a pointer to the function that was previously called by their respective special functions (unexpected() and terminate()). By saving the return values, you can restore the original special functions later so that unexpected() and terminate() will once again call terminate() and abort().

If you use set_terminate() to register your own function, the function should no return to its caller but terminate execution of the program.

Example using the exception handling functions

The following example shows the flow of control and special functions used in exception handling:

```c++
#include <iostream>
#include <exception>
using namespace std;

class X {};
class Y {};
class A {};

// pfv type is pointer to function returning void
typedef void (*pfv)();
```
void my_terminate() {
    cout << "Call to my terminate" << endl;
    abort();
}

void my_unexpected() {
    cout << "Call to my_unexpected()" << endl;
    throw;
}

void f() throw(X, Y, bad_exception) {
    throw A();
}

void g() throw(X, Y) {
    throw A();
}

int main()
{
    pfv old_term = set_terminate(my_terminate);
    pfv old_unex = set_unexpected(my_unexpected);
    try {
        cout << "In first try block" << endl;
        f();
    }
    catch(X) {
        cout << "Caught X" << endl;
    }
    catch(Y) {
        cout << "Caught Y" << endl;
    }
    catch (bad_exception& e1) {
        cout << "Caught bad_exception" << endl;
    }
    catch (...) {
        cout << "Caught some exception" << endl;
    }
    cout << endl;
    try {
        cout << "In second try block" << endl;
        g();
    }
    catch(X) {
        cout << "Caught X" << endl;
    }
    catch(Y) {
        cout << "Caught Y" << endl;
    }
    catch (bad_exception& e2) {
        cout << "Caught bad_exception" << endl;
    }
    catch (...) {
        cout << "Caught some exception" << endl;
    }
}

The following is the output of the above example:
In first try block
Call to my_unexpected()
Caught bad_exception
In second try block
Call to my_unexpected()
Call to my_terminate

At run time, this program behaves as follows:
1. The call to set_terminate() assigns to old_term the address of the function last passed to set_terminate() when set_terminate() was previously called.
2. The call to set_unexpected() assigns to old_unex the address of the function last passed to set_unexpected() when set_unexpected() was previously called.
3. Within the first try block, function f() is called. Because f() throws an unexpected exception, a call to unexpected() is made. unexpected() in turn calls my_unexpected(), which prints a message to standard output. The function my_unexpected() tries to rethrow the exception of type A. Because class A has not been specified in the exception specification of function f(), and bad_exception has been specified, the exception thrown by my_unexpected() is replaced by an exception of type bad_exception.
4. The handler catch (bad_exception& e1) is able to handle the exception.
5. Within the second try block, function g() is called. Because g() throws an unexpected exception, a call to unexpected() is made. unexpected() in turn calls my_unexpected(), which prints a message to standard output. The function my_unexpected() tries to rethrow the exception of type A. Because neither class A nor bad_exception has been specified in the exception specification of function g(), unexpected() calls terminate(), which calls the function my_terminate().
6. my_terminate() displays a message then calls abort(), which terminates the program.
Chapter 17. Preprocessor directives

The preprocessor is a program that is invoked by the compiler to process code before compilation. Commands for that program, known as directives, are lines of the source file beginning with the character #, which distinguishes them from lines of source program text. The effect of each preprocessor directive is a change to the text of the source code, and the result is a new source code file, which does not contain the directives. The preprocessed source code, an intermediate file, must be a valid C or C++ program, because it becomes the input to the compiler.

Preprocessor directives consist of the following:
- Macro definition directives,” which replace tokens in the current file with specified replacement tokens
- “File inclusion directives” on page 399, which embed files within the current file
- “Conditional compilation directives” on page 401, which conditionally compile sections of the current file
- “Message generation directives” on page 405, which control the generation of diagnostic messages
- “The null directive (#)” on page 407, which performs no action
- “Pragma directives” on page 408, which apply compiler-specific rules to specified sections of code

Preprocessor directives begin with the # token followed by a preprocessor keyword. The # token must appear as the first character that is not white space on a line. The # is not part of the directive name and can be separated from the name with white spaces.

A preprocessor directive ends at the new-line character unless the last character of the line is the \ (backslash) character. If the \ character appears as the last character in the preprocessor line, the preprocessor interprets the \ and the new-line character as a continuation marker. The preprocessor deletes the \ (and the following new-line character) and splices the physical source lines into continuous logical lines. White space is allowed between backslash and the end of line character or the physical end of record. However, this white space is usually not visible during editing.

Except for some #pragma directives, preprocessor directives can appear anywhere in a program.

Macro definition directives

Macro definition directives include the following directives and operators:
- “The #define directive,” which defines a macro
- “The #undef directive” on page 396, which removes a macro definition

“Standard predefined macro names” on page 398 describes the macros that are predefined by the ISO C standard.

The #define directive

A preprocessor define directive directs the preprocessor to replace all subsequent occurrences of a macro with specified replacement tokens.

#define directive syntax

```plaintext
#define identifier (identifier-list, ...)
```

© Copyright IBM Corp. 1998, 2011
The #define directive can contain:

- "Object-like macros"
- "Function-like macros" on page 393

The following are some differences between #define and the const type qualifier:

- The #define directive can be used to create a name for a numerical, character, or string constant, whereas a const object of any type can be declared.
- A const object is subject to the scoping rules for variables, whereas a constant created using #define is not.
- Unlike a const object, the value of a macro does not appear in the intermediate source code used by the compiler because they are expanded inline. The inline expansion makes the macro value unavailable to the debugger.
- A macro can be used in a constant expression, such as a bit field length, whereas a const object cannot.
- The compiler does not type-check a macro, including macro arguments.

Object-like macros

An object-like macro definition replaces a single identifier with the specified replacement tokens. The following object-like definition causes the preprocessor to replace all subsequent instances of the identifier COUNT with the constant 1000:

```
#define COUNT 1000
```

If the statement

```
int arry[COUNT];
```

appears after this definition and in the same file as the definition, the preprocessor would change the statement to

```
int arry[1000];
```

in the output of the preprocessor.

Other definitions can make reference to the identifier COUNT:

```
#define MAX_COUNT COUNT + 100
```

The preprocessor replaces each subsequent occurrence of MAX_COUNT with COUNT + 100, which the preprocessor then replaces with 1000 + 100.

If a number that is partially built by a macro expansion is produced, the preprocessor does not consider the result to be a single value. For example, the following will not result in the value 10.2 but in a syntax error.

```
#define a 10
a.2
```

In C++0x, the diagnostic for object-like macros in the C99 preprocessor is adopted to provide a common preprocessor interface for C and C++ compilers. The C++0x compiler issues a warning message if there are no white spaces between an object-like macro name and its replacement list in a macro definition. For more information, see “C99 preprocessor features adopted in C++0x” on page 409.
Function-like macros

More complex than object-like macros, a function-like macro definition declares the names of formal parameters within parentheses, separated by commas. An empty formal parameter list is legal: such a macro can be used to simulate a function that takes no arguments. C99 adds support for function-like macros with a variable number of arguments.

Function-like macro definition:
An identifier followed by a parameter list in parentheses and the replacement tokens. The parameters are imbedded in the replacement code. White space cannot separate the identifier (which is the name of the macro) and the left parenthesis of the parameter list. A comma must separate each parameter.

For portability, you should not have more than 31 parameters for a macro. The parameter list may end with an ellipsis (...) as the formal parameter. In this case, the identifier __VA_ARGS__ may appear in the replacement list.

Function-like macro invocation:
An identifier followed by a comma-separated list of arguments in parentheses. The number of arguments should match the number of parameters in the macro definition, unless the parameter list in the definition ends with an ellipsis. In this latter case, the number of arguments in the invocation should exceed the number of parameters in the definition. The excess are called trailing arguments. Once the preprocessor identifies a function-like macro invocation, argument substitution takes place. A parameter in the replacement code is replaced by the corresponding argument. If trailing arguments are permitted by the macro definition, they are merged with the intervening commas to replace the identifier __VA_ARGS__, as if they were a single argument. Any macro invocations contained in the argument itself are completely replaced before the argument replaces its corresponding parameter in the replacement code.

A macro argument can be empty (consisting of zero preprocessing tokens). For example,
#define SUM(a,b,c) a + b + c
SUM(1,,3) /* No error message.
1 is substituted for a, 3 is substituted for c. */

If the identifier list does not end with an ellipsis, the number of arguments in a macro invocation must be the same as the number of parameters in the corresponding macro definition. During parameter substitution, any arguments remaining after all specified arguments have been substituted (including any separating commas) are combined into one argument called the variable argument. The variable argument will replace any occurrence of the identifier __VA_ARGS__ in the replacement list. The following example illustrates this:
#define debug(...) fprintf(stderr, __VA_ARGS__)
debug("flag"); /* Becomes fprintf(stderr, "flag"); */

Commas in the macro invocation argument list do not act as argument separators when they are:
- In character constants
- In string literals
- Surrounded by parentheses

The following line defines the macro SUM as having two parameters a and b and the replacement tokens (a + b):
#define SUM(a,b) (a + b)

This definition would cause the preprocessor to change the following statements (if the statements appear after the previous definition):
c = SUM(x,y);
c = d * SUM(x,y);
In the output of the preprocessor, these statements would appear as:
\[
c = (x + y);
c = d * (x + y);
\]

Use parentheses to ensure correct evaluation of replacement text. For example, the definition:
\[
#define SQR(c) ((c) * (c))
\]
requires parentheses around each parameter \(c\) in the definition in order to correctly evaluate an expression like:
\[
y = SQR(a + b);
\]

The preprocessor expands this statement to:
\[
y = ((a + b) * (a + b));
\]

Without parentheses in the definition, the correct order of evaluation is not preserved, and the preprocessor output is:
\[
y = (a + b = a + b);
\]

Arguments of the \# and \## operators are converted before replacement of parameters in a function-like macro.

Once defined, a preprocessor identifier remains defined and in scope independent of the scoping rules of the language. The scope of a macro definition begins at the definition and does not end until a corresponding \#undef directive is encountered. If there is no corresponding \#undef directive, the scope of the macro definition lasts until the end of the translation unit.

A recursive macro is not fully expanded. For example, the definition
\[
#define x(a,b) x(a+1,b+1) + 4
\]
expands
\[
x(20,10)
\]
to
\[
x(20+1,10+1) + 4
\]
rather than trying to expand the macro \(x\) over and over within itself. After the macro \(x\) is expanded, it is a call to function \(x()\).

A definition is not required to specify replacement tokens. The following definition removes all instances of the token \debug\ from subsequent lines in the current file:
\[
#define debug
\]
You can change the definition of a defined identifier or macro with a second preprocessor \#define directive only if the second preprocessor \#define directive is preceded by a preprocessor \#undef directive. The \#undef directive nullifies the first definition so that the same identifier can be used in a redefinition.

Within the text of the program, the preprocessor does not scan character constants or string constants for macro invocations.

The following example program contains two macro definitions and a macro invocation that refers to both of the defined macros:

CCNRAA8
/**
** This example illustrates #define directives.
**/

#include <stdio.h>

#define SQR(s) ((s) * (s))
#define PRNT(a,b) 
  printf("value 1 = %d\n", a); \ 
  printf("value 2 = %d\n", b)

int main(void)
{
  int x = 2;
  int y = 3;

       PRNT(SQR(x),y);

  return(0);
}

After being interpreted by the preprocessor, this program is replaced by code equivalent to the following:

CCNRAA9
#include <stdio.h>
int main(void)
{
  int x = 2;
  int y = 3;

       printf("value 1 = %d\n", ( (x) * (x) ) );
       printf("value 2 = %d\n", y);

  return(0);
}

This program produces the following output:
value 1 = 4
value 2 = 3

IBM

Variadic macro extensions

Variadic macro extensions refer to two extensions to C99 and Standard C++ related to macros with variable number of arguments. One extension is a mechanism for renaming the variable argument identifier from __VA_ARGS__ to a user-defined identifier. The other extension provides a way to remove the dangling comma in a variadic macro when no variable arguments are specified. Both extensions have been implemented to facilitate porting programs developed with GNU C and C++.

The following examples demonstrate the use of an identifier in place of __VA_ARGS__. The first definition of the macro debug exemplifies the usual usage of __VA_ARGS__. The second definition shows the use of the identifier args in place of __VA_ARGS__.

#define debug1(format, ...) printf(format, ## __VA_ARGS__)
#define debug2(format, args ...) printf(format, ## args)

<table>
<thead>
<tr>
<th>Invocation</th>
<th>Result of macro expansion</th>
</tr>
</thead>
<tbody>
<tr>
<td>debug1(&quot;Hello %s/n.&quot;World&quot;);</td>
<td>printf(&quot;Hello %s/n.&quot;World&quot;);</td>
</tr>
<tr>
<td>debug2(&quot;Hello %s/n.&quot;World&quot;);</td>
<td>printf(&quot;Hello %s/n.&quot;World&quot;);</td>
</tr>
</tbody>
</table>
The preprocessor removes the trailing comma if the variable arguments to a function macro are omitted or empty and the comma followed by ## precedes the variable argument identifier in the function macro definition.

In C++0x, the variadic macros feature and changes concerning empty macro arguments are adopted from the C99 preprocessor to provide a common preprocessor interface for C and C++ compilers. Variadic macros and empty macro arguments are supported in C++0x. For more information, see "C99 preprocessor features adopted in C++0x" on page 409.

- "Operator precedence and associativity" on page 158
- "Parenthesized expressions ( )" on page 120

The #undef directive

A preprocessor undef directive causes the preprocessor to end the scope of a preprocessor definition.

#undef directive syntax

```c
#define BUFFER 512
#define SQR(x) ((x) * (x))
```

The following directives define BUFFER and SQR:

```c
#define BUFFER 512
#define SQR(x) ((x) * (x))
```

The following directives nullify these definitions:

```c
#undef BUFFER
#undef SQR
```

Any occurrences of the identifiers BUFFER and SQR that follow these #undef directives are not replaced with any replacement tokens. Once the definition of a macro has been removed by an #undef directive, the identifier can be used in a new #define directive.

The # operator

The # (single number sign) operator converts a parameter of a function-like macro into a character string literal. For example, if macro ABC is defined using the following directive:

```c
#define ABC(x) #x
```

all subsequent invocations of the macro ABC would be expanded into a character string literal containing the argument passed to ABC. For example:

<table>
<thead>
<tr>
<th>Invocation</th>
<th>Result of macro expansion</th>
</tr>
</thead>
<tbody>
<tr>
<td>ABC(1)</td>
<td>&quot;1&quot;</td>
</tr>
<tr>
<td>ABC(Hello there)</td>
<td>&quot;Hello there&quot;</td>
</tr>
</tbody>
</table>

The # operator should not be confused with the null directive.

Use the # operator in a function-like macro definition according to the following rules:
• A parameter following # operator in a function-like macro is converted into a character string literal containing the argument passed to the macro.

• White-space characters that appear before or after the argument passed to the macro are deleted.

• Multiple white-space characters imbedded within the argument passed to the macro are replaced by a single space character.

• If the argument passed to the macro contains a string literal and if a \ (backslash) character appears within the literal, a second \ character is inserted before the original \ when the macro is expanded.

• If the argument passed to the macro contains a " (double quotation mark) character, a \ character is inserted before the " when the macro is expanded.

• The conversion of an argument into a string literal occurs before macro expansion on that argument.

• If more than one ## operator or # operator appears in the replacement list of a macro definition, the order of evaluation of the operators is not defined.

• If the result of the macro expansion is not a valid character string literal, the behavior is undefined.

The following examples demonstrate the use of the # operator:

```c
#define STR(x) #x
#define XSTR(x) STR(x)
#define ONE 1

Invocation | Result of macro expansion
---|---
STR(\n "\n" \n') | "\n \"\n\n \n"
STR(ONE) | "ONE"
XSTR(ONE) | "1"
XSTR("hello") | "\hello\""
```

"The null directive (#)" on page 407

### The ## operator

The ## (double number sign) operator concatenates two tokens in a macro invocation (text and/or arguments) given in a macro definition.

If a macro `XY` was defined using the following directive:

```c
#define XY(x,y) x##y
```

the last token of the argument for `x` is concatenated with the first token of the argument for `y`.

Use the ## operator according to the following rules:

• The ## operator cannot be the very first or very last item in the replacement list of a macro definition.

• The last token of the item in front of the ## operator is concatenated with first token of the item following the ## operator.

• Concatenation takes place before any macros in arguments are expanded.

• If the result of a concatenation is a valid macro name, it is available for further replacement even if it appears in a context in which it would not normally be available.

• If more than one ## operator and/or # operator appears in the replacement list of a macro definition, the order of evaluation of the operators is not defined.

The following examples demonstrate the use of the ## operator:

```c
#define ArgArg(x, y) x##y
#define ArgText(x) x##TEXT
#define TextArg(x) TEXT##x
```

"The #define directive" on page 391

Standard predefined macro names

Both C and C++ provide the following predefined macro names as specified in the ISO C language standard. Except for __FILE__ and __LINE__, the value of the predefined macros remains constant throughout the translation unit.

__DATE__
A character string literal containing the date when the source file was compiled.

The value of __DATE__ changes as the compiler processes any include files that are part of your source program. The date is in the form:
"Mmm dd yyyy"

where:

Mmm Represents the month in an abbreviated form (Jan, Feb, Mar, Apr, May, Jun, Jul, Aug, Sep, Oct, Nov, or Dec).

dd Represents the day. If the day is less than 10, the first d is a blank character.

yyy Represents the year.

__FILE__
A character string literal containing the name of the source file.

The value of __FILE__ changes as the compiler processes include files that are part of your source program. It can be set with the #line directive.

__LINE__
An integer representing the current source line number.

The value of __LINE__ changes during compilation as the compiler processes subsequent lines of your source program. It can be set with the #line directive.

__STDC__
For C, the integer 1 (one) indicates that the C compiler supports the ISO standard. If you set the language level to COMMONC, this macro is undefined. (When a macro is undefined, it behaves as if it had the integer value 0 when used in a #if statement.)

For C++, this macro is predefined to have the value 0 (zero). This indicates that the C++ language is not a proper superset of C, and that the compiler does not conform to ISO C.

__STDC_HOSTED__ (C only)
The value of this C99 macro is 1, indicating that the C compiler is a hosted implementation. Note that this macro is only defined if __STDC__ is also defined.
__STDC_VERSION__ (C only)
The integer constant of type long int: 199409L for the C89 language level, 199901L for C99. Note that this macro is only defined if __STDC__ is also defined.

__TIME__
A character string literal containing the time when the source file was compiled.
The value of __TIME__ changes as the compiler processes any include files that are part of your source program. The time is in the form:

"hh:mm:ss"

where:

hh Represents the hour.

mm Represents the minutes.

ss Represents the seconds.

__cplusplus (C++ only)
For C++ programs, this macro expands to the long integer literal 199711L, indicating that the compiler is a C++ compiler. For C programs, this macro is not defined. Note that this macro name has no trailing underscores.

Object-like macros

File inclusion directives

File inclusion directives consist of:

• "The #include directive," which inserts text from another source file

• "The #include_next directive (IBM extension)" on page 401, which causes the compiler to omit the directory of the including file from the search path when searching for include files

The #include directive

A preprocessor include directive causes the preprocessor to replace the directive with the contents of the specified file.

#include directive syntax

```
#include "file_name"
```

z/OS You can specify a data set or a z/OS UNIX System Services file for file_name. Use double slashes (///<) before the file_name to indicate that the file is a data set. Use a single slash (/) anywhere in the file_name to indicate a z/OS UNIX System Services file.

If the file_name is enclosed in double quotation marks, for example:

```
#include "payroll1.h"
```

it is treated as a user-defined file, and may represent a header or source file.
If the file_name is enclosed in angle brackets, for example:

```
#include <stdio.h>
```

it is treated as a system-defined file, and must represent a header file.

The new-line and > characters cannot appear in a file name delimited by < and >. The new-line and " (double quotation marks) characters cannot appear in a file name delimited by " and ", although > can.

The file_path can be an absolute or relative path. If the double quotation marks are used, and file_path is a relative path, or is not specified, the preprocessor adds the directory of the including file to the list of paths to be searched for the included file. If the double angle brackets are used, and file_path is a relative path, or is not specified, the preprocessor does not add the directory of the including file to the list of paths to be searched for the included file.

The preprocessor resolves macros contained in an #include directive. After macro replacement, the resulting token sequence consists of a file name enclosed in either double quotation marks or the characters < and >. For example:

```
#define MONTH <july.h>
#include MONTH
```

Declarations that are used by several files can be placed in one file and included with #include in each file that uses them. For example, the following file defs.h contains several definitions and an inclusion of an additional file of declarations:

```
/* defs.h */
#define TRUE 1
#define FALSE 0
#define BUFFERSIZE 512
#define MAX_ROW 66
#define MAX_COLUMN 80
int hour;
int min;
int sec;
#include "mydefs.h"
```

You can embed the definitions that appear in defs.h with the following directive:

```
#include "defs.h"
```

In the following example, a #define combines several preprocessor macros to define a macro that represents the name of the C standard I/O header file. A #include makes the header file available to the program.

```
#define C_IO_HEADER <stdio.h>
/* The following is equivalent to:
  *  #include <stdio.h>
  */
#include C_IO_HEADER
```

The z/OS implementation has specially defined behavior and compiler options for include file search paths, which are documented in greater detail in the descriptions of the SEARCH and LSEARCH options in the z/OS XL C/C++ User's Guide.

In C++0x, the changes to header and include file names in the C99 preprocessor are adopted to provide a common preprocessor interface for C and C++ compilers. The first character of a header file name in an #include directive must not be a digit in C++0x. For more information, see "C99 preprocessor features adopted in C++0x" on page 409.
The \texttt{\#include\_next} directive (IBM extension)

The preprocessor directive \texttt{\#include\_next} behaves like the \texttt{\#include} directive, except that it specifically excludes the directory of the including file from the paths to be searched for the named file. All search paths up to and including the directory of the including file are omitted from the list of paths to be searched for the included file. This allows you to include multiple versions of a file with the same name in different parts of an application; or to include one header file in another header file with the same name (without the header including itself recursively). Provided that the different file versions are stored in different directories, the directive ensures you can access each version of the file, without requiring that you use absolute paths to specify the file name.

\texttt{\#include\_next} directive syntax

\begin{verbatim}
/SM590000/SM590000 #include\_next "file\_name"
\end{verbatim}

The directive must only be used in header files, and the file specified by the \texttt{file\_name} must be a header file. There is no distinction between the use of double quotation marks and angle brackets to enclose the file name. You can specify a data set for \texttt{file\_name}. Use double slashes (//) before the \texttt{file\_name} to indicate that the file is a data set.

As an example of how search paths are resolved with the \texttt{\#include\_next} directive, assume that there are two versions of the file \texttt{t.h}: the first one, which is included in the source file \texttt{t.c}, is located in the subdirectory \texttt{path1}; the second one, which is included in the first one, is located in the subdirectory \texttt{path2}. Both directories are specified as include file search paths when \texttt{t.c} is compiled.

\begin{verbatim}
/* t.c */
#include "t.h"
int main()
{
    printf("\, ret\_val\);
}
/* t.h in path1 */
#include\_next "t.h"
int ret\_val = RET;
/* t.h in path2 */
#define RET 55;
\end{verbatim}

The \texttt{\#include\_next} directive instructs the preprocessor to skip the \texttt{path1} directory and start the search for the included file from the \texttt{path2} directory. This directive allows you to use two different versions of \texttt{t.h} and it prevents \texttt{t.h} from being included recursively.

\section*{Conditional compilation directives}

A \textit{preprocessor conditional compilation directive} causes the preprocessor to conditionally suppress the compilation of portions of source code. These directives test a constant expression or an identifier to determine which tokens the preprocessor should pass on to the compiler and which tokens should be bypassed during preprocessing. The directives are:
The #if and #elif directives on page 403, which conditionally include or suppress portions of source code, depending on the result of a constant expression.

The #ifdef directive on page 403, which conditionally includes source text if a macro name is defined.

The #ifndef directive on page 404, which conditionally includes source text if a macro name is not defined.

The #else directive on page 404, which conditionally includes source text if the previous #if, #ifdef, #ifndef, or #elif test fails.

The #endif directive on page 404, which ends conditional text.

The preprocessor conditional compilation directive spans several lines:

- The condition specification line (beginning with #if, #ifdef, or #ifndef)
- Lines containing code that the preprocessor passes on to the compiler if the condition evaluates to a nonzero value (optional)
- The #elif line (optional)
- Lines containing code that the preprocessor passes on to the compiler if the condition evaluates to a nonzero value (optional)
- The #else line (optional)
- Lines containing code that the preprocessor passes on to the compiler if the condition evaluates to zero (optional)
- The preprocessor #endif directive

For each #if, #ifdef, and #ifndef directive, there are zero or more #elif directives, zero or one #else directive, and one matching #endif directive. All the matching directives are considered to be at the same nesting level.

You can nest conditional compilation directives. In the following directives, the first #else is matched with the #if directive.

```c
#ifdef MACNAME
   /* tokens added if MACNAME is defined */
   # if TEST <=10
      /* tokens added if MACNAME is defined and TEST <= 10 */
   # else
      /* tokens added if MACNAME is defined and TEST > 10 */
   # endif
#else
   /* tokens added if MACNAME is not defined */
#endif
```

Each directive controls the block immediately following it. A block consists of all the tokens starting on the line following the directive and ending at the next conditional compilation directive at the same nesting level.

Each directive is processed in the order in which it is encountered. If an expression evaluates to zero, the block following the directive is ignored.

When a block following a preprocessor directive is to be ignored, the tokens are examined only to identify preprocessor directives within that block so that the conditional nesting level can be determined. All tokens other than the name of the directive are ignored.

Only the first block whose expression is nonzero is processed. The remaining blocks at that nesting level are ignored. If none of the blocks at that nesting level has been processed and there is a #else directive, the block following the #else directive is processed. If none of the blocks at that nesting level has been processed and there is no #else directive, the entire nesting level is ignored.
The #if and #elif directives

The #if and #elif directives compare the value of constant_expression to zero:

### #if and #elif directive syntax

```
#define constant_expression token_sequence
```

All macros are expanded, except macros that are the operand of a defined operator. Any uses of the defined operator are processed, and all remaining keywords and identifiers are replaced with the token 0 except true and false.

The behavior is undefined if expanding the macros resulted in the token defined.

**Notes:**
- Casts cannot be performed. For example, the following code can be compiled successfully by both the C and C++ compilers.
  ```c
  #if static_cast<int>(1)
  #error Unexpected
  #endif
  int main() {
  }
  ```
  In C++0x, arithmetic is performed using `long long int` type. See “C99 preprocessor features adopted in C++0x” on page 409 for detailed information.
- The constant_expression can contain defined macros.
- The constant_expression can contain the unary operator defined. This operator can be used only with the preprocessor keyword #if or #elif. The following expressions evaluate to 1 if the identifier is defined in the preprocessor, otherwise to 0:
  ```c
  defined identifier
  defined(identifier)
  ```
  For example:
  ```c
  #if defined(TEST1) || defined(TEST2)
  ```
  - The constant_expression must be an integral constant expression.

If a macro is not defined, a value of 0 (zero) is assigned to it. In the following example, TEST is a macro identifier.

```c
#include <stdio.h>
int main()
{
  #if TEST != 0 // No error even when TEST is not defined.
  printf("Macro TEST is defined to a non-zero value.");
  #endif
  }
```

The #ifdef directive

The #ifdef directive checks for the existence of macro definitions.

If the identifier specified is defined as a macro, the lines of code that immediately follow the condition are passed on to the compiler.
The following example defines MAX_LEN to be 75 if EXTENDED is defined for the preprocessor. Otherwise, MAX_LEN is defined to be 50.

```c
#ifdef EXTENDED
# define MAX_LEN 75
#else
# define MAX_LEN 50
#endif
```

An identifier must follow the #ifndef keyword. The following example defines MAX_LEN to be 50 if EXTENDED is not defined for the preprocessor. Otherwise, MAX_LEN is defined to be 75.

```c
#ifndef EXTENDED
# define MAX_LEN 50
#else
# define MAX_LEN 75
#endif
```

The #else directive

If the condition specified in the #if, #ifdef, or #ifndef directive evaluates to 0, and the conditional compilation directive contains a preprocessor #else directive, the lines of code located between the preprocessor #else directive and the preprocessor #endif directive is selected by the preprocessor to be passed on to the compiler.

```c
#else
token_sequence
#endif
```

The #endif directive

The preprocessor #endif directive ends the conditional compilation directive.

```c
#endif
```
Examples of conditional compilation directives

The following example shows how you can nest preprocessor conditional compilation directives:

```c
#if defined(TARGET1)
#define SIZEOF_INT 16
#else
# define MAX_PHASE 2
#else
# define MAX_PHASE 8
#endif
#endif
 elif defined(TARGET2)
#define SIZEOF_INT 32
#define MAX_PHASE 16
#else
#define SIZEOF_INT 32
#define MAX_PHASE 32
#endif
```

The following program contains preprocessor conditional compilation directives:

```c
CCNRABC
/**
 ** This example contains preprocessor
 ** conditional compilation directives.
 ***/
#include <stdio.h>
int main(void)
{
  static int array[] = { 1, 2, 3, 4, 5};
  int i;
  for (i = 0; i <= 4; i++)
  {
    array[i] *= 2;
    #if TEST >= 1
      printf("i = %d\n", i);
      printf("array[i] = %d\n", array[i]);
    #endif
  }
  return(0);
}
```

Message generation directives

Message generation directives include the following:
- “The #error directive,” which defines text for a compile-time error message
- “The #line directive” on page 406, which supplies a line number for compiler messages

Related reference
- “Conditional compilation directives” on page 401

The #error directive

A preprocessor error directive causes the preprocessor to generate an error message and causes the compilation to fail.
The #error directive is often used in the #else portion of a #if–#elif–#else construct, as a safety check during compilation. For example, #error directives in the source file can prevent code generation if a section of the program is reached that should be bypassed.

For example, the directive
```
#define BUFFER_SIZE 255

#if BUFFER_SIZE < 256
#error "BUFFER_SIZE is too small."
#endif
```
generates the error message:

BUFFER_SIZE is too small.

The #line directive

A preprocessor line control directive supplies line numbers for compiler messages. It causes the compiler to view the line number of the next source line as the specified number.

In order for the compiler to produce meaningful references to line numbers in preprocessed source, the preprocessor inserts #line directives where necessary (for example, at the beginning and after the end of included text).

A file name specification enclosed in double quotation marks can follow the line number. If you specify a file name, the compiler views the next line as part of the specified file. If you do not specify a file name, the compiler views the next line as part of the current source file.

For z/OS XL C/C++ compilers, the file_name should be:
- A fully qualified sequential data set
- A fully qualified PDS or PDSE member
- A z/OS UNIX System Services path name

The entire string is taken unchanged as the alternate source file name for the translation unit (for example, for use by the debugger). Consider if you are using it to redirect the debugger to source lines from this alternate file. In this case, you must ensure the file exists as specified and the line number on the #line directive matches the file contents. The compiler does not check this.

In all C and C++ implementations, the token sequence on a #line directive is subject to macro replacement. After macro replacement, the resulting character sequence must consist of a decimal constant, optionally followed by a file name enclosed in double quotation marks.
You can use `#line` control directives to make the compiler provide more meaningful error messages. The following example program uses `#line` control directives to give each function an easily recognizable line number:

```
CCNRABD
/**
 ** This example illustrates #line directives.
 **/
#include <stdio.h>
#define LINE200 200

int main(void)
{
    func_1();
    func_2();
}

#line 100
func_1()
{
    printf("Func_1 - the current line number is %d\n", __LINE__);}

#line LINE200
func_2()
{
    printf("Func_2 - the current line number is %d\n", __LINE__);}

This program produces the following output:
Func_1 - the current line number is 102
Func_2 - the current line number is 202
```

> **C++0x** In C++0x, the increased limit for `#line` directive from the C99 preprocessor are adopted to provide a common preprocessor interface for C and C++ compilers. The upper limit of `#line <integer>` preprocessor directives has been increased from 32,767 to 2,147,483,647 for the C++ preprocessor in conformance with the C99 preprocessor. For more information, see “C99 preprocessor features adopted in C++0x” on page 409.

## The null directive (#)

The `null directive` performs no action. It consists of a single # on a line of its own.

The null directive should not be confused with the # operator or the character that starts a preprocessor directive.

In the following example, if MINVAL is a defined macro name, no action is performed. If MINVAL is not a defined identifier, it is defined 1.

```
#ifdef MINVAL

#else
    #define MINVAL 1
#endif
```
Pragma directives

A pragma is an implementation-defined instruction to the compiler. It has the general form:

```
#pragma directive syntax
```

The `character_sequence` is a series of characters giving a specific compiler instruction and arguments, if any. The token `STDC` indicates a standard pragma; consequently, no macro substitution takes place on the directive. The `new-line` character must terminate a pragma directive.

The `character_sequence` on a pragma is not subject to macro substitutions.

Note: You can also use the `_Pragma` operator syntax to specify a pragma directive; for details, see “The `_Pragma` preprocessing operator.”

More than one pragma construct can be specified on a single pragma directive. The compiler ignores unrecognized pragmas.

Standard C pragmas are described in “Standard pragmas (C only).” Pragmas available for z/OS XL C/C++ are described in Chapter 18, “z/OS XL C/C++ pragmas,” on page 413.

The `_Pragma` preprocessing operator

The unary operator `_Pragma`, allows a preprocessor macro to be contained in a pragma directive.

```
Pragma operator syntax
```

The `string_literal` can be prefixed with `L`, making it a wide-string literal.

The string literal is destringized and tokenized. The resulting sequence of tokens is processed as if it appeared in a pragma directive. For example, the following two statements are equivalent:

```
Pragma ( "pack(full)" )
#pragma pack(full)
```

In C++0x, the `_Pragma operator` feature of the C99 preprocessor is adopted to provide a common preprocessor interface for C and C++ compilers. The `_Pragma` operator is an alternative method of specifying the `#pragma` directive. For more information, see “C99 preprocessor features adopted in C++0x” on page 409.

Standard pragmas (C only)

A standard pragma is a pragma preprocessor directive for which the C Standard defines the syntax and semantics and for which no macro replacement is performed. A standard pragma must be one of the following:
These pragmas are recognized and ignored.

C99 preprocessor features adopted in C++0x

Note: C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM’s interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

In the C++0x standard, several C99 preprocessor features are adopted to provide a common preprocessor interface for C and C++ compilers. This eases porting C source files to the C++ compiler and eliminates some subtle semantic differences that exist between the old C and C++ preprocessors, thus avoiding preprocessor compatibility issues or diverging preprocessor behaviors.

The following C99 preprocessor features are adopted in C++0x:

- Preprocessor arithmetic with extended integer types
- Mixed string literal concatenation
- Diagnostic for header files and include names
- Increased limit for #line directives
- Diagnostic for object-like macro definitions
- The _Pragma operator
- Variadic macros and empty macro arguments
- Predefined macros

Preprocessor arithmetic with extended integer types

In the C89, C++98, and C++03 preprocessors, integer literals that have int or unsigned int type are widened to long or unsigned long. However, in the C99 and C++0x preprocessors, all signed and unsigned integer types (character types included) are widened to long long or unsigned long long under normal circumstances in XL C/C++.

If this feature is enabled, and both -qnolonglong and -qlanglvl=noc99longlong are set in either -q32 or -q64 modes, the preprocessor still uses long long or unsigned long long representations for all integral and character literals in preprocessor controlling expressions. The following example is valid on the AIX® platform in -q32 mode where the underlying type of wchar_t is unsigned short.

```c
#if L'\x0' - L'\x1' < 0
#error non-C++0x preprocessor arithmetic.
#else
#error C++0x preprocessor arithmetic! L'\x0' and L'\x1' are widened to\n   unsigned long long
#endif
```

The following example shows a case where the long long support is enabled in -q32 mode, this feature causes different inclusion branches to be chosen between the non-C++0x preprocessor and the C++0x preprocessor.

```c
#if ^0ull == 0u + ^0u
#error C++0x preprocessor arithmetic! 0u has the same representation as 0ull,\n   hence ^0ull == 0u + ^0u
```
If this feature is disabled and -qwarn0x is set, the C++0x preprocessor evaluates the controlling expressions in the #if and #elif directives, and compares the evaluation results against that of the non-C++0x preprocessor. If they are different, the compiler warns you that the preprocessor controlling expression evaluates differently between C++0x and non-C++0x language levels.

**Mixed string literal concatenation**

Regular strings can be concatenated with wide-string literals, for example:

```c
#include <wchar.h>
#include <stdio.h>

int main() {
    wprintf(L"Guess what? %ls\n", "I can now concatenate regular strings and wide strings!
    printf("Guess what? %ls\n", L"I can now concatenate strings this way too!");
}
```

This example prints the following output when it is executed:

Guess what? I can now concatenate regular strings and wide strings!  
Guess what? I can now concatenate strings this way too!

**Diagnostic for header files and include names**

When this feature is enabled, if the first character of a header file name in an #include directive is a digit, the compiler issues a warning message. Consider the following example:

```
//inc.C
#include "0x/mylib.h"
int main() {
    return 0;
}
```

When compiling or preprocessing this example with this feature enabled, the compiler issues the following warning message:

```
"inc.C", line 1.10: 1540-0893 (W) The header file name "0x/mylib.h" in #include directive shall not start with a digit.
```

**Increased limit for #line directives**

The upper limit of the #line <integer> preprocessor directives has been increased from 32,767 to 2,147,483,647 for the C++0x preprocessor in conformance with the C99 preprocessor.

```c
#line 1000000 //Valid in C++0x, but invalid in C++98
int main() {
    return 0;
}
```
Diagnostic for object-like macro definitions

If there is no white space between object-like macro name and its replacement list in a macro definition, the C++0x compiler issues a warning message. Consider the following example:

```
//w.C

//With -qnodollar, '$' is not part of the macro name,
//thus it begins the replacement list
#define A$B c
#define STR2(x) #x
#define STR(x) STR2(x)
char x[] = STR(A$B);
```

When compiling or preprocessing this example with this feature enabled and -qnodollar is specified, the compiler issues the following warning message:

"w.C", line 1.10: 1540-0891 (W) Missing white space between the identifier "A" and the replacement list.

The _Pragma operator

The _Pragma operator is an alternative method of specifying #pragma directives. For example, the following two statements are equivalent:

```
#pragma comment(copyright, "IBM 2010")
Pragma("comment(copyright, "IBM 2010")")
```

The string IBM 2010 is inserted into the C++ object file when the following code is compiled:

```
int main()
{
    return 0;
}
```

Variadic macros and empty macro arguments

Variadic macros and empty macro arguments are supported in C99 and C++0x. This feature enables a mechanism that renames the variable argument identifier from __VA_ARGS__ to a user-defined identifier. Consider the following example:

```
#define debug(...) fprintf(stderr, __VA_ARGS__)
#define showlist(...) puts(#__VA_ARGS__)
#define report(test, ...) ((test)?puts(#test): printf(__VA_ARGS__))
#define debug("Flag");
debug("X = %d\n", x);
showlist(The first, second, and third items.);
report(x>y, "x is %d but y is %d", x, y);
```

This example is expanded to the following code after preprocessing:

```
fprintf(stderr, "Flag");
fprintf(stderr, "X = %d\n", x);
puts("The first, second, and third items.");
((x>y)?puts("x>y"): printf("x is %d but y is %d", x, y));
```

Predefined macros

The __STDC_HOSTED__ macro is predefined to 1, regardless of whether the following macros are defined or not:

- __STDC__
- __STDC_VERSION__
- __STDC_ISO_10646__

Chapter 18. z/OS XL C/C++ pragmas

The following sections describe the pragmas available in z/OS XL C/C++:

- "Pragma directive syntax"
- "Scope of pragma directives"
- "IPA effects" on page 414
- "Summary of compiler pragmas by functional category" on page 414
- "Individual pragma descriptions" on page 418

Pragma directive syntax

z/OS XL C/C++ supports the following pragma directive:

```
#pragma
```

This form uses the following syntax:

```
#pragma name (suboptions)
```

The `name` is the pragma directive name, and the `suboptions` are any required or optional suboptions that can be specified for the pragma, where applicable.

You can specify more than one `name` and `suboptions` in a single `#pragma` statement.

The compiler ignores unrecognized pragmas, issuing an informational message indicating this.

If you have any pragmas that are not common to both C and C++ in code that will be compiled by both compilers, you may add conditional compilation directives around the pragmas. (This is not strictly necessary since unrecognized pragmas are ignored.) For example, `#pragma object_model` is only recognized by the C++ compiler, so you may decide to add conditional compilation directives around the pragma.

```
#ifdef __cplusplus
#pragma object_model(pop)
#endif
```

Scope of pragma directives

Many pragma directives can be specified at any point within the source code in a compilation unit; others must be specified before any other directives or source code statements. In the individual descriptions for each pragma, the "Usage" section describes any constraints on the pragma’s placement.

In general, if you specify a pragma directive before any code in your source program, it applies to the entire compilation unit, including any header files that are included. For a directive that can appear anywhere in your source code, it applies from the point at which it is specified, until the end of the compilation unit.

You can further restrict the scope of a pragma’s application by using complementary pairs of pragma directives around a selected section of code. For example, using `#pragma checkout (suspend)` and `#pragma checkout (resume)` directives as follows requests that the selected parts of your source code be excluded from being diagnosed by the CHECKOUT compiler option:

```
#pragma checkout (suspend)
```
#pragma checkout (suspend)
/*Source code between the suspend and resume pragma
   checkout is excluded from CHECKOUT analysis*/
#pragma checkout (resume)

Many pragmas provide "pop" or "reset" suboptions that allow you to enable and disable pragma settings in a stack-based fashion; examples of these are provided in the relevant pragma descriptions.

IPA effects

Interprocedural Analysis (IPA), through the IPA compiler option, is a mechanism for performing optimizations across the translation units of your C or C++ program. IPA also performs optimizations not otherwise available with the z/OS XL C/C++ compiler.

You may see changes during the IPA link step, due to the effect of a pragma. The IPA link step detects and resolves the conflicting effects of pragmas, and the conflicting effects of pragmas and compiler options that you specified for different translation units. There may also be conflicting effects between pragmas and equivalent compiler options that you specified for the IPA link step.

IPA resolves these conflicts similar to the way it resolves conflicting effects of compiler options that are specified for the IPA compile step and the IPA link step. The compiler Options Map section of the IPA link step listing shows the conflicting effects between compiler options and pragmas, along with the resolutions.

Summary of compiler pragmas by functional category

The z/OS XL C/C++ pragmas available on the z/OS platform are grouped into the following categories:

- "Language element control"
- "C++ template pragmas" on page 415
- "Floating point and integer control" on page 415
- "Error checking and debugging" on page 415
- "Listings, messages and compiler information" on page 415
- "Optimization and tuning" on page 416
- "Object code control" on page 416
- "Portability and migration" on page 417

For descriptions of these categories, see "Summary of compiler options" in the z/OS XL C/C++ User's Guide.

Language element control

Table 31. Language element control pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>#pragma extension on page 432</td>
<td>Enables extended language features.</td>
</tr>
<tr>
<td>#pragma filetag on page 433</td>
<td>Specifies the code set in which the source code was entered.</td>
</tr>
<tr>
<td>#pragma langlvl directive (C only) on page 441</td>
<td>Determines whether source code and compiler options should be checked for conformance to a specific language standard, or subset or superset of a standard.</td>
</tr>
<tr>
<td>#pragma margins on page 448, nomargins</td>
<td>Specifies the columns in the input line to scan for input to the compiler.</td>
</tr>
</tbody>
</table>
Table 31. Language element control pragmas (continued)

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;#pragma options (C only)&quot; on page 458</td>
<td>Specifies a list of compiler options that are to be processed as if you had typed them on the command line or on the CPARM parameter of the IBM-supplied catalogued procedures.</td>
</tr>
<tr>
<td>&quot;#pragma runopts&quot; on page 468</td>
<td>Specifies a list of runtime options for the compiler to use at execution time.</td>
</tr>
<tr>
<td>&quot;#pragma sequence&quot; on page 469</td>
<td>Defines the section of the input record that is to contain sequence numbers.</td>
</tr>
<tr>
<td>&quot;#pragma XOPTS&quot; on page 478</td>
<td>Passes suboptions directly to the CICS integrated translator for processing CICS statements embedded in C/C++ source code.</td>
</tr>
</tbody>
</table>

C++ template pragmas

Table 32. C++ template pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;#pragma define (C++ only)&quot; on page 425</td>
<td>Provides an alternative method for explicitly instantiating a template class.</td>
</tr>
<tr>
<td>&quot;#pragma do_not_instantiate (C++ only)&quot; on page 427</td>
<td>Prevents the specified template declaration from being instantiated.</td>
</tr>
<tr>
<td>&quot;#pragma implementation (C++ only)&quot; on page 435</td>
<td>For use with the TEMPINC compiler option, supplies the name of the file containing the template definitions corresponding to the template declarations contained in a header file.</td>
</tr>
</tbody>
</table>

Floating point and integer control

Table 33. Floating point and integer control pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>#pragma chars</td>
<td>Determines whether all variables of type char are treated as either signed or unsigned.</td>
</tr>
<tr>
<td>&quot;#pragma enum&quot; on page 427</td>
<td>Specifies the amount of storage occupied by enumerations.</td>
</tr>
</tbody>
</table>

Error checking and debugging

Table 34. Error checking and debugging pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;#pragma operator_new (C++ only)&quot; on page 455</td>
<td>Determines whether the new and new[] operators throw an exception if the requested memory cannot be allocated.</td>
</tr>
</tbody>
</table>

Listings, messages and compiler information

Table 35. Listings, messages and compiler information pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;#pragma checkout&quot; on page 419</td>
<td>Controls the diagnostic messages that are generated by the compiler.</td>
</tr>
</tbody>
</table>
### Table 35. Listings, messages and compiler information pragmas (continued)

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>#pragma info (C++ only)</code></td>
<td>on page 436: Controls the diagnostic messages that are generated by the compiler.</td>
</tr>
<tr>
<td><code>#pragma page (C only)</code></td>
<td>on page 463: Specifies that the code following the pragma begins at the top of the page in the generated source listing.</td>
</tr>
<tr>
<td><code>#pragma pagesize (C only)</code></td>
<td>on page 463: Sets the number of lines per page for the generated source listing.</td>
</tr>
<tr>
<td><code>#pragma report (C++ only)</code></td>
<td>on page 467: Controls the generation of diagnostic messages.</td>
</tr>
<tr>
<td><code>#pragma skip (C only)</code></td>
<td>on page 470: Skips lines of the generated source listing.</td>
</tr>
<tr>
<td><code>#pragma subtitle (C only)</code></td>
<td>on page 472: Places subtitle text on all subsequent pages of the generated source listing.</td>
</tr>
<tr>
<td><code>#pragma title (C only)</code></td>
<td>on page 473: Places title text on all subsequent pages of the generated source listing.</td>
</tr>
</tbody>
</table>

### Optimization and tuning

**Table 36. Optimization and tuning pragmas**

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>#pragma disjoint</code></td>
<td>on page 425: Lists identifiers that are not aliased to each other within the scope of their use.</td>
</tr>
<tr>
<td><code>#pragma execution_frequency</code></td>
<td>on page 429: Marks program source code that you expect will be either very frequently or very infrequently executed.</td>
</tr>
<tr>
<td><code>#pragma inline (C only) / noinline</code></td>
<td>on page 437: Specifies that a C function is to be inlined, or that a C or C++ function is not to be inlined.</td>
</tr>
<tr>
<td><code>#pragma isolated_call</code></td>
<td>Specifies functions in the source file that have no side effects other than those implied by their parameters.</td>
</tr>
<tr>
<td><code>#pragma leaves</code></td>
<td>on page 442: Informs the compiler that a named function never returns to the instruction following a call to that function.</td>
</tr>
<tr>
<td><code>#pragma option_override</code></td>
<td>on page 456: Allows you to specify optimization options at the subprogram level that override optimization options given on the command line.</td>
</tr>
<tr>
<td><code>#pragma reachable</code></td>
<td>on page 466: Informs the compiler that the point in the program after a named function can be the target of a branch from some unknown location.</td>
</tr>
<tr>
<td><code>#pragma unroll</code></td>
<td>Controls loop unrolling, for improved performance.</td>
</tr>
</tbody>
</table>

### Object code control

**Table 37. Object code control pragmas**

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>#pragma comment</code></td>
<td>on page 420: Places a comment into the object module.</td>
</tr>
<tr>
<td><code>#pragma csect</code></td>
<td>on page 423: Identifies the name for the code, static, or test control section (CSECT) of the object module.</td>
</tr>
<tr>
<td><code>#pragma environment (C only)</code></td>
<td>on page 429: Uses C code as an assembler substitute.</td>
</tr>
</tbody>
</table>
Table 37. Object code control pragmas (continued)

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>#pragma export</code> on page 431</td>
<td>Declares that an external function or variable is to be exported.</td>
</tr>
<tr>
<td><code>#pragma hashome (C++ only)</code> on page 434</td>
<td>Informs the compiler that the specified class has a home module that will be specified by <code>#pragma ishome</code>.</td>
</tr>
<tr>
<td><code>#pragma insert_asm (C only)</code> on page 438</td>
<td>Enables users to provide additional assembler statements that are inserted into the compiler-generated High-Level Assembler (HLASM) code.</td>
</tr>
<tr>
<td><code>#pragma ishome (C++ only)</code> on page 438</td>
<td>Informs the compiler that the specified class's home module is the current compilation unit.</td>
</tr>
<tr>
<td><code>#pragma linkage (C only)</code> on page 443</td>
<td>Identifies the entry point of modules that are used in interlanguage calls from C programs as well as the linkage or calling convention that is used on a function call.</td>
</tr>
<tr>
<td><code>#pragma longname/nolongname</code> on page 445, nolongname</td>
<td>Specifies whether the compiler is to generate mixed-case names that can be longer than 8 characters in the object module.</td>
</tr>
<tr>
<td><code>#pragma map</code> on page 447</td>
<td>Converts all references to an identifier to another, externally defined identifier.</td>
</tr>
<tr>
<td><code>#pragma pack</code> on page 459</td>
<td>Sets the alignment of all aggregate members to a specified byte boundary.</td>
</tr>
<tr>
<td><code>#pragma priority (C++ only)</code></td>
<td>Specifies the priority level for the initialization of static objects.</td>
</tr>
<tr>
<td><code>#pragma prolog (C only), #pragma epilog (C only)</code> on page 464</td>
<td>When used with the METAL option, inserts High-Level Assembly (HLASM) prolog or epilog code for a specified function.</td>
</tr>
<tr>
<td><code>#pragma strings</code></td>
<td>Specifies the storage type for string literals.</td>
</tr>
<tr>
<td><code>#pragma target (C only)</code> on page 472</td>
<td>Specifies the operating system or runtime environment for which the compiler creates the object module.</td>
</tr>
<tr>
<td><code>#pragma variable</code> on page 475</td>
<td>Specifies whether the compiler is to use a named external object in a reentrant or non-reentrant fashion.</td>
</tr>
</tbody>
</table>

Portability and migration

Table 38. Portability and migration pragmas

<table>
<thead>
<tr>
<th>Pragma</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>#pragma convert</code> on page 421</td>
<td>Provides a way to specify more than one coded character set in a single compilation unit to convert string literals.</td>
</tr>
<tr>
<td><code>#pragma convlit</code> on page 423</td>
<td>Suspends the string literal conversion that the CONVLIT compiler option performs during specific portions of your program.</td>
</tr>
<tr>
<td><code>#pragma namemangling (C++ only)</code> on page 449</td>
<td>Chooses the name mangling scheme for external symbol names generated from C++ source code.</td>
</tr>
<tr>
<td><code>#pragma namemanglingrule (C++ only)</code> on page 451</td>
<td>Provides fined-grained control over the name mangling scheme in effect for selected portions of source code, specifically with respect to the mangling of cv-qualifiers in function parameters.</td>
</tr>
<tr>
<td><code>#pragma object_model (C++ only)</code> on page 454</td>
<td>Sets the object model to be used for structures, unions, and classes.</td>
</tr>
<tr>
<td><code>#pragma wsizeof</code> on page 477</td>
<td>Toggles the behavior of the <code>sizeof</code> operator between that of a compiler prior the C/C++ for MVS/ESA V3R2 and the z/OS XL C/C++ compiler.</td>
</tr>
</tbody>
</table>
Individual pragma descriptions

This section contains descriptions of individual pragmas available in z/OS XL C/C++.

For each pragma, the following information is given:

Category
The functional category to which the pragma belongs is listed here.

Purpose
This section provides a brief description of the effect of the pragma, and why you might want to use it.

Syntax
This section provides the syntax for the pragma. For convenience, the #pragma name form of the directive is used in each case. However (in C), it is perfectly valid to use the alternate C99-style _Pragma operator syntax; see “Pragma directive syntax” on page 413 for details.

Parameters
This section describes the suboptions that are available for the pragma, where applicable.

Usage
This section describes any rules or usage considerations you should be aware of when using the pragma. These can include restrictions on the pragma’s applicability, valid placement of the pragma, and so on.

IPA effects
For those pragmas where there are special considerations for IPA, the pragma descriptions include IPA-related information.

Examples
Where appropriate, examples of pragma directive use are provided in this section.

#pragma chars

Category
Floating-point and integer control

Purpose
Determines whether all variables of type char are treated as either signed or unsigned.

Syntax
Pragma syntax

```
#pragma chars ( [signed] )
```

Defaults
-qchars=unsigned

Parameters

```
unsigned
```
Variables of type char are treated as unsigned char.

```
signed
```
Variables of type char are treated as signed char.
Usage

Regardless of the setting of this pragma, the type of char is still considered to be distinct from the types unsigned char and signed char for purposes of type-compatibility checking or C++ overloading.

If the pragma is specified more than once in the source file, the first one will take precedence. Once specified, the pragma applies to the entire file and cannot be disabled; if a source file contains any functions that you want to compile without #pragma chars, place these functions in a different file.

The pragma must appear before any source statements, except for the pragmas filetag, longname, langlvl or target, which may precede it.

Related information
• The CHARS option in the z/OS XL C/C++ User’s Guide.

#pragma checkout

Category

“Listings, messages and compiler information” on page 415

Purpose

Controls the diagnostic messages that are generated by the compiler.

You can suspend the diagnostics that the INFO or CHECKOUT compiler options perform during specific portions of your program. You can then resume the same level of diagnostics later in the file.

You can use this pragma directive in place of the INFO option or #pragma info directive.

Syntax

C

```c
#pragma checkout( resume, suspend )
```

C++

```c
#pragma checkout( suboption )
```

Defaults

See the INFO and CHECKOUT options in the z/OS XL C/C++ User’s Guide.

Parameters

C++ suboption

Any suboption supported by the INFO compiler option. For details, see the INFO option in the z/OS XL C/C++ User’s Guide.

suspend

Instructs the compiler to suspend all diagnostic operations for the code following the directive.
resume

Instructs the compiler to resume all diagnostic operations for the code following the directive.

Usage

This pragma can appear anywhere that a preprocessor directive is valid.

Related information

- "#pragma info (C++ only)" on page 436
- The INFO and CHECKOUT options in the z/OS XL C/C++ User's Guide.

#pragma comment

Category

Object code control

Purpose

Places a comment into the object module.

Syntax

C++

```c++
#pragma comment ( compiler )
```

c

```c
#pragma comment ( compiler )
```

Parameters

**compiler**

Appends the name and version of the compiler in an END information record at the end of the generated object module. The name and version are not included in the generated executable, nor are they loaded into memory when the program is run.

**date**

The date and time of the compilation are appended in an END information record at the end of the generated object module. The date and time are not included in the generated executable, nor are they loaded into memory when the program is run.

**timestamp**

Appends the date and time of the last modification of the source in an END information record at the end of the generated object module. The date and time are not included in the generated executable, nor are they loaded into memory when the program is run.
If the compiler cannot find the timestamp for a source file, the directive returns Mon Jan 1 0:00:01
1990.
copyright
Places the text specified by the token_sequence, if any, into the generated object module. The
token_sequence is included in the generated executable and loaded into memory when the program is
run.
C

csect_copyright
Places the text specified by the token_sequence, if any, into a CSECT section named csect_name in
the generated object module. token_sequence is included in the generated executable and loaded into
memory when the program is run.

C

csect_name
The user-specified csect_name should not conflict with CODE, STATIC or TEST CSECT names
specified using #pragma csect.

user
Places the text specified by the token_sequence, if any, into the generated object module. The
characters are placed in two locations in the generated object module. One copy of the string is
placed in the code image so that the string will be included in the executable load module. This copy
is not necessarily loaded into memory when the program is run. A second copy of the string is placed
on the END records in columns 34 to 71 for XOBJ-format object modules, or in columns 4 to 80 for
GOFF-format object modules.
token_sequence
The characters in this field, if specified, must be enclosed in double quotation marks ("). This field has
a 32767-byte limit.

Usage
More than one comment directive can appear in a translation unit, and each type of comment directive
can appear more than once, with the exception of copyright, which can appear only once.
You can display the object-file comments by using the MAP option for the C370LIB utility.

IPA effects
This directive affects the IPA compile step only if the OBJECT suboption of the IPA compiler option is in
effect.
During the IPA link step, the compiler may combine multiple objects into one. In the case where multiple
csect_copyright comment directives are found, the compiler will keep one and discard the rest.
During the partitioning process in the IPA link step, the compiler places the text string information #pragma
comment at the beginning of a partition.

#pragma convert
Category
“Portability and migration” on page 417

Purpose
Provides a way to specify more than one coded character set in a single compilation unit to convert string
literals.

Chapter 18. z/OS XL C/C++ pragmas

421


Unlike the related CONVLIT, ASCII/EBDCIC, and LOCALE compiler options, it allows for more than one character encoding to be used for string literals in the same compilation unit.

Syntax

```
#pragma convert(ccsid) "code_set_name"
```

Defaults

See the z/OS XL C/C++ User's Guide for information about default code pages.

Parameters

**ccsid**

Represents the Coded Character Set Identifier, which is an integer value between 0 and 65535 inclusive. The coded character set can be based on either EBCDIC or ASCII.

**code_set_name**

Is a string that specifies an ASCII or EBCDIC based codepage.

**base**

Represents the codepage determined by the current locale or the LOCALE compiler option. If the ASCII option has been specified, then `base` is the ISO8859-1 codepage; if the CONVLIT option has been specified, then `base` is the codepage indicated by that option. If both ASCII and CONVLIT options have been specified, then `base` is the codepage indicated by the CONVLIT option.

**source**

Represents the codepage the source file is written in; that is, the filetag. If there is no filetag, then `source` is the codepage indicated by the LOCALE option specified at compile time.

**pop**

Resets the code set to that which was previously in effect immediately before the current codepage.

**pop_all**

Resets the codepage to that which was in effect before the introduction of any `convert` pragmas.

Usage

The compiler options CONVLIT, ASCII/EBDCIC, and LOCALE determine the code set in effect before any `#pragma convert` directives are introduced, and after all `#pragma convert` directives are popped from the stack.

The conversion continues from the point of placement of the first `#pragma convert` directive until another `#pragma convert` directive is encountered, or until the end of the source file is reached. For every `#pragma convert` directive in your program, it is good practice to have a corresponding `#pragma convert(pop)` as well. This will prevent one file from potentially changing the codepage of another file that is included.

`#pragma convert` takes precedence over `#pragma convlit`.

The following are not converted:

- A string or character constant specified in hexadecimal or octal escape sequence format (because it represents the value of the desired character on output).
- A string literal that is part of a `#include` or pragma directive.
• String literals that are used to specify linkage (for example, extern "C").

Related information
• "#pragma convlit"
• The LOCALE, ASCII, and CONVLIT options in the z/OS XL C/C++ User's Guide.

#pragma convlit
Category
"Portability and migration" on page 417

Purpose
Suspends the string literal conversion that the CONVLIT compiler option performs during specific portions of your program.

You can then resume the conversion at some later point in the file.

Syntax
```
#pragma convlit (suspend) (resume)
```

Defaults
See the z/OS XL C/C++ User's Guide for information about default code pages.

Parameters
suspend
Instructs the compiler to suspend all string literal conversions for the code following the directive.

resume
Instructs the compiler to resume all string literal conversions for the code following the directive.

Usage
If you use the PPONLY option, the compiler echoes the convlit pragma to the expanded source file.

Related information
• "#pragma convert" on page 421
• The CONVLIT option in the z/OS XL C/C++ User's Guide.

#pragma csect
Category
"Object code control" on page 416

Purpose
Identifies the name for the code, static, or test control section (CSECT) of the object module.

Syntax
Defaults

See the CSECT option in the z/OS XL C/C++ User's Guide.

Parameters

CODE
Specifies the CSECT that contains the executable code (C functions) and constant data.

STATIC
Designates the CSECT that contains all program variables with the static storage class and all character strings.

TEST
Designates the CSECT that contains debug information. You must also specify the TEST compiler option.

name
The name that is used for the applicable CSECT. The compiler does not map the name in any way. If the name is greater than 8 characters, the LONGNAME option must be in effect and you must use the binder. The name must not conflict with the name of an exposed name (external function or object) in a source file. In addition, it must not conflict with another #pragma csect directive or #pragma map directive. For example, the name of the code CSECT must differ from the name of the static and test CSECTs. For more information on CSECT naming rules, see the CSECT compiler option description in the z/OS XL C/C++ User's Guide.

Usage

At most, three #pragma csect directives can appear in a source program as follows:
- One for the code CSECT
- One for the static CSECT
- One for the debug CSECT

When both #pragma csect and the CSECT compiler option are specified, the compiler first uses the option to generate the CSECT names, and then the #pragma csect overrides the names generated by the option.

Examples

Suppose that you compile the following code with the option CSECT(abc) and program name foo.c.

```c
#pragma csect (STATIC, "blah")
int main ()
{
    return 0;
}
```

First, the compiler generates the following csect names:

- STATIC: abc#foo#S
- CODE: abc#foo#C
- TEST: abc#foo#T

Then the #pragma csect overrides the static CSECT name, which renders the final CSECT name to be:
IPA effects

Use the \texttt{#pragma csect} directive when naming regular objects only if the OBJECT suboption of the IPA compiler option is in effect. Otherwise, the compiler discards the CSECT names that \texttt{#pragma csect} generated.

Related information

\begin{itemize}
  \item CSECT option in the \textit{z/OS XL C/C++ User's Guide}.
\end{itemize}

\textbf{#pragma define (C++ only)}

Category

\texttt{Template control}

Purpose

Provides an alternative method for explicitly instantiating a template class.

Syntax

\begin{verbatim}
# pragma define(template_class_name)
\end{verbatim}

Parameters

\begin{itemize}
  \item template\_class\_name
\end{itemize}

The name of the template class to be instantiated.

Usage

This pragma provides the equivalent functionality to C++ explicit instantiation definitions. It is provided for compatibility with earlier releases only. New applications should use C++ explicit instantiation definitions.

This pragma can appear anywhere an explicit instantiation definition can appear.

Examples

The following directive:

\begin{verbatim}
#pragma define(Array<char>)
\end{verbatim}

is equivalent to the following explicit instantiation:

\begin{verbatim}
template class Array<char>;
\end{verbatim}

Related information

\begin{itemize}
  \item "Explicit instantiation" on page 345
\end{itemize}
Purpose

Lists identifiers that are not aliased to each other within the scope of their use.

By informing the compiler that none of the identifiers listed in the pragma shares the same physical storage, the pragma provides more opportunity for optimizations.

Syntax

```
#pragma disjoint ( variable_name, variable_name )
```

Parameters

`variable_name`

The name of a variable. It must not refer to any of the following:
- A member of a structure, class, or union
- A structure, union, or enumeration tag
- An enumeration constant
- A `typedef` name
- A label

Usage

The `#pragma disjoint` directive asserts that none of the identifiers listed in the pragma share physical storage; if any the identifiers do actually share physical storage, the pragma may give incorrect results.

The pragma can appear anywhere in the source program that a declaration is allowed. An identifier in the directive must be visible at the point in the program where the pragma appears.

You must declare the identifiers before using them in the pragma. Your program must not dereference a pointer in the identifier list nor use it as a function argument before it appears in the directive.

Examples

The following example shows the use of `#pragma disjoint`.

```c
int a, b, *ptr_a, *ptr_b;

#pragma disjoint(*ptr_a, b) /* *ptr_a never points to b */
#pragma disjoint(*ptr_b, a) /* *ptr_b never points to a */

one_function()
{
    b = 6;
    *ptr_a = 7; /* Assignment will not change the value of b */

    another_function(b); /* Argument "b" has the value 6 */
}
```

External pointer `ptr_a` does not share storage with and never points to the external variable `b`. Consequently, assigning 7 to the object to which `ptr_a` points will not change the value of `b`. Likewise, external pointer `ptr_b` does not share storage with and never points to the external variable `a`. The compiler can assume that the argument to `another_function` has the value 6 and will not reload the variable from memory.
#pragma do_not_instantiate (C++ only)

**Category**

Template control

**Purpose**

Prevents the specified template declaration from being instantiated.

You can use this pragma to suppress the implicit instantiation of a template for which a definition is supplied.

**Syntax**

```c
#pragma do_not_instantiate template_class_name
```

**Parameters**

`template_class_name`

The name of the template class that should not be instantiated.

**Usage**

If you are handling template instantiations manually (that is, NOTEMPINC and NOTEMPLATEREGISTRY are specified), and the specified template instantiation already exists in another compilation unit, using `#pragma do_not_instantiate` ensures that you do not get multiple symbol definitions during the link step.

**C++0x**

`#pragma do_not_instantiate` on a class template specialization is treated as an explicit instantiation declaration of the specialization. This pragma provides a subset of the functionality of standard C++0x explicit instantiation declarations. It is provided for compatibility purposes only and is not recommended. New applications should use standard C++0x explicit instantiation declarations instead.

**Examples**

The following shows the usage of the pragma:

```c
#pragma do_not_instantiate Stack < int >
```

**Related information**

- "#pragma define (C++ only)" on page 425

#pragma enum

**Category**

"Floating point and integer control" on page 415

**Purpose**

Specifies the amount of storage occupied by enumerations.

**Syntax**
Defaults

The default is small.

Parameters

small
Specifies that an enumeration occupies the minimum amount of storage required by the smallest predefined type that can represent that range of enumeration constants: either 1, 2, or 4 bytes of storage. If the specified storage size is smaller than that required by the range of the enumeration constants, the compiler issues a diagnostic message. For example:

```c
#pragma enum(1)
enum e_tag {
    a=0,
    b=SHRT_MAX /* diagnostic message */
} e_var;
#pragma enum(reset)
```

int
Specifies that an enumeration occupies 4 bytes of storage and is represented by int.

1 Specifies that an enumeration occupies 1 byte of storage.

2 Specifies that an enumeration occupies 2 bytes of storage.

4 Specifies that an enumeration occupies 4 bytes of storage.

8 Specifies that an enumeration occupies 8 bytes of storage. This suboption is only valid with LP64.

C++ intlong
Specifies that an enumeration occupies 8 bytes of storage and is represented as a long if the range of the enumeration constants exceeds the limit for type int. Otherwise, enumerations occupy 4 bytes of storage and are of type int. This suboption is only valid with LP64.

reset
pop
Sets the enum setting to that which was in effect before the current setting.

Usage

The directive is in effect until the next valid #pragma enum directive is encountered. For every #pragma enum directive in your program, it is good practice to have a corresponding #pragma enum(reset) or #pragma enum(pop) as well. This is the only way to prevent one file from potentially changing the enum setting of another file that is included.

You cannot have #pragma enum directives within the declaration of an enumeration. The following code segment generates a warning message and the second occurrence of the pragma is ignored:

```c
#pragma enum(small)
enum e_tag {
    a,
```
b,
#pragma enum(int) /*cannot be within a declaration*/
c
} e_var;

Related information

For detailed information on the preferred sign and type for each range of enumeration constants, see the description of the ENUMSIZE compiler option in the z/OS XL C/C++ User's Guide.

#pragma environment (C only)
Category

“Object code control” on page 416

Purpose

Uses C code as an assembler substitute.

The directive allows you to do the following:
• Specify a function as an entry point other than main
• Omit setting up a C environment on entry to the named function
• Specify several system exits that are written in C code in the same executable

Syntax

```
#pragma environment (identifier[,nolib])
```

Defaults

Not applicable.

Parameters

identifier

The name of the function that is to be the alternate entry point.

nolib

The Language Environment is established, but the LE runtime library is not loaded at run time. If you omit this argument, the library is loaded.

Usage

If you specify any other value than nolib after the function name, behavior is not defined.

#pragma execution_frequency
Category

“Optimization and tuning” on page 416

Purpose

Marks program source code that you expect will be either very frequently or very infrequently executed.

When optimization is enabled, the pragma is used as a hint to the optimizer.
Syntax

```
#pragma execution_frequency(very_low)
```

Parameters

**very_low**
Marks source code that you expect will be executed very infrequently.

**very_high**
Marks source code that you expect will be executed very frequently.

Usage

Use this pragma in conjunction with an optimization option; if optimization is not enabled, the pragma has no effect.

The pragma must be placed within block scope, and acts on the closest point of branching.

Examples

In the following example, the pragma is used in an if statement block to mark code that is executed infrequently.

```c
int *array = (int *) malloc(10000);
if (array == NULL) {
    /* Block A */
    #pragma execution_frequency(very_low)
    error();
}
```

In the next example, the code block Block B is marked as infrequently executed and Block C is likely to be chosen during branching.

```c
if (Foo > 0) {
    #pragma execution_frequency(very_low)
    /* Block B */
    doSomething();
} else {
    /* Block C */
    doAnotherThing();
}
```

In this example, the pragma is used in a switch statement block to mark code that is executed frequently.

```c
while (counter > 0) {
    #pragma execution_frequency(very_high)
    doSomething();
} /* This loop is very likely to be executed. */

switch (a) {
    case 1:
        doOneThing();
        break;
    case 2:
        #pragma execution_frequency(very_high)
        doTwoThings();
        break;
    default:
        doNothing();
} /* The second case is frequently chosen. */
```
The following example shows how the pragma must be applied at block scope and affects the closest branching.

```c
int a;
#pragma execution_frequency(very_low)
int b;

int foo(boolean boo) {
    #pragma execution_frequency(very_low)
    char c;
    if (boo) {
        /* Block A */
        doSomething();
        {
            /* Block C */
            doSomethingAgain();
            #pragma execution_frequency(very_low)
            doAnotherThing();
        }
    } else {
        /* Block B */
        doNothing();
    }
    return 0;
}
#pragma execution_frequency(very_low)
```

**#pragma export**

**Category**

“Object code control” on page 416

**Purpose**

Declares that an external function or variable is to be exported.

The pragma also specifies the name of the function or variable to be referenced outside the module. You can use this pragma to export functions or variables from a DLL module.

**Syntax**

```
#pragma export
```

**Defaults**

Not applicable.

**Parameters**

`identifier`

The name of a variable or function to be exported.
Usage

You can specify this pragma anywhere in the DLL source code, on its own line, or with other pragmas. You can also specify it before or after the definition of the variable or function. You must externally define the exported function or variable.

If the specification for a `const` variable in a `#pragma export` directive conflicts with the ROCONST option, the pragma directive takes precedence over the compiler option, and the compiler issues an informational message. The `const` variable gets exported and it is considered reentrant.

The `main` function cannot be exported.

IPA effects

If you specify this pragma in your source code in the IPA compile step, you cannot override the effects of this pragma on the IPA link step.

Related reference

- “The _Export qualifier (C++ only)” on page 105
- “The _Export function specifier (C++ only)” on page 197

#pragma extension

Category

“Language element control” on page 414

Purpose

Enables extended language features.

Syntax

```
#pragma extension
```

Defaults

See the description of the LANGLVL compiler option in the z/OS XL C/C++ User's Guide.

Parameters

pop

Reverts the language level setting to the previous one defined for the file (if any).

Usage

The directive must only occur outside external declarations.

Multiple `#pragma extension` and `#pragma extension(pop)` directive pairs can appear in the same file. You should place a `#pragma extension(pop)` directive at the end of the section of code to which the `#pragma extension` applies within the same file; if you do not do so, the compiler will insert a pop directive.

Do not pop a `#pragma extension` directive from within a nested include file.
When `#pragma langlvl` is embedded in `#pragma extension` and `#pragma extension (pop)` directives, an informational message is issued and `#pragma langlvl` is ignored.

**Examples**

The following example shows how `#pragma extension` is applied to an included file, assuming that the default language level setting is ANSI:

```c
#pragma extension
#include_next <stddef.h> /* C++: langlvl = extended; C: langlvl = extc89 */
#pragma extension (pop)
#include <pthread.h> /* langlvl = ansi */
```

The following example shows how `#pragma extension` is applied to a section of code, assuming that the default language level setting is ANSI:

```c
int alignofChar()
{
    return __alignof__(char); /* langlvl = ansi, __alignof__ is treated as an
                                identifier and an error message
                                is issued */
}
#pragma extension

int alignofInt() /* C++: langlvl = extended; C: langlvl = extc89 */
{
    return __alignof__(int); /* __alignof__ is treated as a keyword
                                and no error message is issued */
}
```

**Related information**

- [“#pragma langlvl directive (C only)” on page 441](#)
- The LANGLVL option in the *z/OS XL C/C++ User’s Guide*.

### #pragma filetag

**Category**

“Language element control” on page 414

**Purpose**

Specifies the code set in which the source code was entered.

**Syntax**

```
#pragma filetag ("code_set_name")
```

**Defaults**

See the *z/OS XL C/C++ User’s Guide* for information about default code pages.

**Parameters**

`code_set_name`

The name of the source code set.
Usage

Since the # character is variant between code sets, use the trigraph representation ??= instead of # as illustrated below.

The #pragma filetag directive can appear only once per source file. It must appear before the first statement or directive, except for conditional compilation directives or the #line directive. For example:

```c
??=line 42
??=ifdef COMPILER_VER /* This is allowed. */
??=pragma filetag ("code set name")
??=endif
```

The #pragma filetag directive should not appear in combination with any other #pragma directives. For example, the following is incorrect:

```c
??=pragma filetag ("IBM-1047") export (baffle_1)
```

If there are comments before the pragma, the compiler does not translate them to the code page that is associated with the LOCALE option.

Related information

- The LOCALE, ASCII, and CONVLIT options in the z/OS XL C/C++ User's Guide.

#pragma hashome (C++ only)

Category

Object code control

Purpose

Informs the compiler that the specified class has a home module that will be specified by #pragma ishome.

This class's virtual function table, along with certain inline functions, will not be generated as static. Instead, they will be referenced as externals in the compilation unit of the class in which #pragma ishome is specified.

Syntax

```c
# pragma hashome (class_name [allinlines])
```

Parameters

class_name

The name of a class to be referenced externally. class_name must be a class and it must be defined.

allinlines

Specifies that all inline functions from within class_name should be referenced as being external.

Usage

A warning will be produced if there is a #pragma ishome without a matching #pragma hashome.
Examples

In the following example, compiling the code samples will generate virtual function tables and the definition of \texttt{S::foo()} only for compilation unit \texttt{a.o}, but not for \texttt{b.o}. This reduces the amount of code generated for the application.

\begin{verbatim}
// a.h
struct S
{
    virtual void foo() {}
    virtual void bar();
};

// a.C
#pragma ishome(S)
#pragma hashome(S)
#include "a.h"
int main()
{
    S s;
    s.foo();
    s.bar();
}

// b.C
#pragma hashome(S)
#include "a.h"
void S::bar() {}
\end{verbatim}

Related information

- "\#pragma ishome (C++ only)" on page 438

\textbf{\#pragma implementation (C++ only)}

Category

[Template control]

Purpose

For use with the TEMPINC compiler option, supplies the name of the file containing the template definitions corresponding to the template declarations contained in a header file.

Syntax

\begin{verbatim}
\#pragma implementation("file_name")
\end{verbatim}

Parameters

\textit{file_name}

- The name of the file containing the definitions for members of template classes declared in the header file.
Usage

This pragma is not normally required if your template implementation file has the same name as the
header file containing the template declarations, and a .c extension. You only need to use the pragma if
the template implementation file does not conform to this file-naming convention. For more information
about using template implementation files, see “Using templates in C++ programs” in the z/OS XL C/C++
Programming Guide.

#pragma implementation is only effective if the TEMPIINC option is in effect. Otherwise, the pragma has
no meaning and is ignored.

The pragma can appear in the header file containing the template declarations, or in a source file that
includes the header file. It can appear anywhere that a declaration is allowed.

Related information

- The TEMPIINC option in the z/OS XL C/C++ User's Guide.
- “Using templates in C++ programs” in the z/OS XL C/C++ Programming Guide.

#pragma info (C++ only)

Category

“Listings, messages and compiler information” on page 415

Purpose

Controls the diagnostic messages that are generated by the compiler.

You can use this pragma directive in place of the INFO option.

Syntax

```plaintext
#pragma info(suboption,
suspend, resume)
```

Defaults

See the INFO option in the z/OS XL C/C++ User's Guide.

Parameters

suboption

Any suboption allowed by the INFO compiler option. For details, see the description of the INFO
option in the z/OS XL C/C++ User's Guide.

suspend

Suspends the diagnostics that the pragma or INFO compiler option performs during specific portions of
your program.

resume

Resumes the same level of diagnostics in effect before the suspend pragma was specified.

Related information

- “#pragma checkout” on page 419
- The INFO option in the z/OS XL C/C++ User's Guide.
#pragma inline (C only) / noinline

**Category**

"Optimization and tuning" on page 416

**Purpose**

Specifies that a C function is to be inlined, or that a C or C++ function is not to be inlined.

**Syntax**

- C
  
  ```
  #pragma inline (identifier)
  ```
  
  ```
  #pragma noinline (identifier)
  ```

- C++
  
  ```
  #pragma noinline (identifier)
  ```

**Defaults**

The default is **noinline**.

**Parameters**

- **inline**
  
  Inlines the named function on every call, provided you have specified the INLINE or the OPT compiler options (otherwise it has no effect). The function is inlined in both selective (NOAUTO) and automatic (AUTO) mode.

- **noinline**
  
  Prevents the named function from being inlined on any call, disabling any effects of the INLINE or OPT compiler options (the pragma has no effect in selective (NOAUTO) mode). It also takes precedence over the C/C++ keyword **inline**.

- **identifier**
  
  The name of a function to be included or excluded for inlining.

**Usage**

- C
  
  The directive must be at file scope.

- C++
  
  The directive can be placed anywhere.

**IPA effects**

If you use either the **#pragma inline** or the **#pragma noinline** directive in your source, you can later override them with an appropriate IPA link control file directive during the IPA link step. The compiler uses the IPA link control file directive in the following cases:

- If you specify both the **#pragma noinline** directive and the IPA link control file **inline** directive for a function.
- If you specify both the **#pragma inline** directive and the IPA link control file **noinline** directive for a function.
Related information

- "The inline function specifier" on page 192
- The INLINE option in the z/OS XL C/C++ User's Guide.

#pragma insert_asm (C only)

Category

"Object code control" on page 416

Purpose

Enables users to provide additional assembler statements that are inserted into the compiler-generated High-Level Assembler (HLASM) code.

Syntax

```
#pragma insert_asm("assembler_statement")
```

Defaults

Not applicable.

Parameters

`assembler_statement`

Valid assembler statement inserted into the generated HLASM code.

Usage

`#pragma insert_asm` can be used with a `_Pragma` operator. You must use the "\" character before double quotation marks when specifying the statements in the `_Pragma` operator; for example, `_Pragma ("insert_asm("MYSTATEMENT")")`.

Multiple `insert_asm` pragmas can be specified in a program. The compiler will insert the statements into the generated HLASM in the order they are specified. The statements are inserted at the end of the compiler-generated code for the compilation unit and are placed before the END statement.

The compiler does not have any knowledge of the contents of the specified statements. You must ensure that the statements do not cause assembly errors when compiling the final HLASM code.

You must specify the METAL compiler option in order to use `#pragma insert_asm`. For more information on the METAL compiler option, see z/OS XL C/C++ User's Guide.

IPA effects

Not applicable.

#pragma ishome (C++ only)

Category

"Object code control"

Purpose

Informs the compiler that the specified class's home module is the current compilation unit.

438  z/OS V1R13.0 XL C/C++ Language Reference
The home module is where items, such as the virtual function table, are stored. If an item is referenced from outside of the compilation unit, it will not be generated outside its home. This can reduce the amount of code generated for the application.

Syntax

```c
#pragma ishome (class_name)
```

Parameters

`class_name`

The name of the class whose home will be the current compilation unit.

Usage

A warning will be produced if there is a `#pragma ishome` without a matching `#pragma hashome`.

Examples

See “`#pragma hashome (C++ only)” on page 434` on page 434

Related information

- “`#pragma hashome (C++ only)” on page 434` on page 434

`#pragma isolated_call`

Category

Optimization and tuning

Purpose

Specifies functions in the source file that have no side effects other than those implied by their parameters.

Essentially, any change in the state of the runtime environment is considered a side effect, including:

- Accessing a volatile object
- Modifying an external object
- Modifying a static object
- Modifying a file
- Accessing a file that is modified by another process or thread
- Allocating a dynamic object, unless it is released before returning
- Releasing a dynamic object, unless it was allocated during the same invocation
- Changing system state, such as rounding mode or exception handling
- Calling a function that does any of the above

Marking a function as isolated indicates to the optimizer that external and static variables cannot be changed by the called function and that pessimistic references to storage can be deleted from the calling function where appropriate. Instructions can be reordered with more freedom, resulting in fewer pipeline delays and faster execution in the processor. Multiple calls to the same function with identical parameters can be combined, calls can be deleted if their results are not needed, and the order of calls can be changed.
Syntax

Pragma syntax

```c
#pragma isolated_call(function)
```

Defaults

Not applicable.

Parameters

`function`

The name of a function that does not have side effects or does not rely on functions or processes that have side effects. `function` is a primary expression that can be an identifier, operator function, conversion function, or qualified name. An identifier must be of type function or a `typedef` of function.

If the name refers to an overloaded function, all variants of that function are marked as isolated calls.

Usage

The only side effect that is allowed for a function named in the pragma is modifying the storage pointed to by any pointer arguments passed to the function, that is, calls by reference. The function is also permitted to examine non-volatile external objects and return a result that depends on the non-volatile state of the runtime environment. Do not specify a function that causes any other side effects; that calls itself; or that relies on local static storage. If a function is incorrectly identified as having no side effects, the program behavior might be unexpected or produce incorrect results.

The `#pragma isolated_call` directive can be placed at any point in the source file, before or after calls to the function named in the pragma.

Predefined macros

None.

Examples

The following example shows you when to use the `#pragma isolated_call` directive (on the `addmult` function). It also shows you when not to use it (on the `same` and `check` functions):

```c
#include <stdio.h>
#include <math.h>

int addmult(int op1, int op2);
#pragma isolated_call(addmult)

/* This function is a good candidate to be flagged as isolated as its */
/* result is constant with constant input and it has no side effects. */
int addmult(int op1, int op2) {
    int rslt;
    rslt = op1*op2 + op2;
    return rslt;
}

/* The function 'same' should not be flagged as isolated as its state */
/* (the static variable delta) can change when it is called. */
int same(double op1, double op2) {
    static double delta = 1.0;
    double temp;
```
temp = (op1-op2)/op1;
if (fabs(temp) < delta)
   return 1;
else {
   delta = delta / 2;
   return 0;
}
}

/* The function 'check' should not be flagged as isolated as it has a */
/* side effect of possibly emitting output. */
int check(int op1, int op2) {
   if (op1 < op2)
      return -1;
   if (op1 > op2)
      return 1;
   printf("Operands are the same.\n");
   return 0;
}

IPA effects

If you specify this pragma in your source code in the IPA compile step, you cannot override the effects of the pragma on the IPA link step.

#pragma langlvl directive (C only)

Category

"Language element control" on page 414

Purpose

Determines whether source code and compiler options should be checked for conformance to a specific language standard, or subset or superset of a standard.

This pragma is equivalent to the LANGLVL compiler option.

Syntax

```
#define pragma langlvl( ansi )
```

Defaults

See the LANGLVL option in the z/OS XL C/C++ User's Guide.

Parameters

ansi

Allows only language constructs that support the ISO C standards. It does not permit packed decimal types and issues an error message when it detects assignment between integral types and pointer types.
extc89
  Allows language constructs that support the ISO C89 standard, and accepts implementation-specific
  language extensions.

extc99
  Allows language constructs that support the ISO C99 standard, and accepts implementation-specific
  language extensions.

extended
  The option permits packed decimal types and it issues a warning message when it detects assignment
  between integral types and pointer types.

commonc
  Allows compilation of code that contains constructs defined by the X/Open Portability Guide (XPG)
  Issue 3 C language (referred to as Common Usage C). It is roughly equivalent to K&R C.

saa
  Compilation conforms to the IBM SAA C Level 2 CPI language definition.

saal2
  Compilation conforms to the SAA C Level 2 CPI language definition, with some exceptions.

stdc89
  Allows language constructs that support the ISO C89 standard.

stdc99
  Allows language constructs that support the ISO C99 standard.

Usage

You can only specify this pragma only once in a source file, and must appear before any statements. The
compiler uses predefined macros in the header files to make declarations and definitions available that
define the specified language level. When both the pragma and the compiler option are specified, the
compiler option takes precedence over the pragma. Note that if you would like to specify the extc89
language level, you can also do by using #pragma extension.

Note: In z/OS UNIX System Services, if the c89 environment variable (_NOCMDOPTS) is set to 1,
#pragma langlvl has no effect. You must use the compiler option LANGLVL instead of the pragma.

Related information
  • “Standard pragmas (C only)” on page 408
  • “#pragma extension” on page 432
  • The LANGLVL option in the z/OS XL C/C++ User's Guide.

#pragma leaves

Category

Optimization and tuning

Purpose

Informs the compiler that a named function never returns to the instruction following a call to that function.

By informing the compiler that it can ignore any code after the function, the directive allows for additional
opportunities for optimization.

This pragma is commonly used for custom error-handling functions, in which programs can be terminated
if a certain error is encountered.
#pragma leaves

**Syntax**

```c
#pragma leaves(function_name)
```

**Parameters**

`function_name`

The name of the function that does not return to the instruction following the call to it.

**Defaults**

Not applicable.

**Usage**

If you specify the LIBANSI compiler option (which informs the compiler that function names that match functions in the C standard library are in fact C library functions), the compiler checks whether the `longjmp` family of functions (`longjmp`, `_longjmp`, `siglongjmp`, and `_siglongjmp`) contain `#pragma leaves`. If the functions do not contain this pragma directive, the compiler will insert this directive for the functions. This is not shown in the listing.

**Examples**

```c
#pragma leaves(handle_error_and_quit)
void test_value(int value)
{
  if (value == ERROR_VALUE)
  {
    handle_error_and_quit(value);
    TryAgain(); // optimizer ignores this because
    // never returns to execute it
  }
}
```

**IPA effects**

If you specify the `#pragma leaves` directive in your source code in the IPA compile step, you cannot override the effects of this directive in the IPA link step.

**Related information**

- "#pragma reachable" on page 466.

**#pragma linkage (C only)**

**Category**

"Object code control" on page 416

**Purpose**

Identifies the entry point of modules that are used in interlanguage calls from C programs as well as the linkage or calling convention that is used on a function call.

The directive also designates other entry points within a program that you can use in a fetch operation.
## Syntax

```c
#pragma linkage(identifier, OS)
```

### Parameters

**identifier**

The name of a function that is to be the entry point of the module, or a typedef name that will be used to define the entry point. (See below for an example.)

**FETCHABLE**

Indicates that `identifier` can be used in a `fetch` operation. A fetched XPLINK module must have its entry point defined with a `#pragma linkage(..., fetchable)` directive.

**OS**

Designates `identifier` as an OS linkage entry point. OS linkage is the basic linkage convention that is used by the operating system. If the caller is compiled with NOXPLINK, on entry to the called routine, its register 13 points to a standard Language Environment stack frame, beginning with a 72-byte save area. The stack frame is compatible with Language Environment languages that expect by-reference calling conventions and with the Language Environment-supplied assembler prologue macro. If the caller is compiled with XPLINK, the behavior depends on the OSCALL suboption of the XPLINK compiler option. This suboption selects the behavior for linkage OS from among OS_DOWNSTACK, OS_UPSTACK, and OS_NOSTACK (the default). This means that applications which use linkage OS to communicate among C or C++ functions will need source changes when recompiled with XPLINK. See the description that follows for REFERENCE.

**PLI**

Designates `identifier` as a PL/I linkage entry point.

**COBOL**

Designates `identifier` as a COBOL linkage entry point.

**FORTRAN**

Designates `identifier` as a FORTRAN linkage entry point.

**RETURNCODE** indicates to the compiler that the routine named by `identifier` is a FORTRAN routine, which returns an alternate return code. It also indicates that the routine is defined outside the translation unit. You can retrieve the return code by using the `fortrc` function. If the compiler finds the function definition inside the translation unit, it issues an error message. Note that you can define functions outside the translation unit, even if you do not specify the RETURNCODE keyword.

**OS_DOWNSTACK**

Designates `identifier` as an OS linkage entry point in XPLINK mode with a downward growing stack frame.

If the function identified by `identifier` is defined within the translation unit and is compiled using the NOXPLINK option, the compiler issues an error message.

### Defaults

C linkage.

### Parameters

- **identifier**
  The name of a function that is to be the entry point of the module, or a typedef name that will be used to define the entry point. (See below for an example.)

- **FETCHABLE**
  Indicates that `identifier` can be used in a fetch operation. A fetched XPLINK module must have its entry point defined with a `#pragma linkage(..., fetchable)` directive.

- **OS**
  Designates `identifier` as an OS linkage entry point. OS linkage is the basic linkage convention that is used by the operating system. If the caller is compiled with NOXPLINK, on entry to the called routine, its register 13 points to a standard Language Environment stack frame, beginning with a 72-byte save area. The stack frame is compatible with Language Environment languages that expect by-reference calling conventions and with the Language Environment-supplied assembler prologue macro. If the caller is compiled with XPLINK, the behavior depends on the OSCALL suboption of the XPLINK compiler option. This suboption selects the behavior for linkage OS from among OS_DOWNSTACK, OS_UPSTACK, and OS_NOSTACK (the default). This means that applications which use linkage OS to communicate among C or C++ functions will need source changes when recompiled with XPLINK. See the description that follows for REFERENCE.

- **PLI**
  Designates `identifier` as a PL/I linkage entry point.

- **COBOL**
  Designates `identifier` as a COBOL linkage entry point.

- **FORTRAN**
  Designates `identifier` as a FORTRAN linkage entry point.

- **RETURNCODE** indicates to the compiler that the routine named by `identifier` is a FORTRAN routine, which returns an alternate return code. It also indicates that the routine is defined outside the translation unit. You can retrieve the return code by using the `fortrc` function. If the compiler finds the function definition inside the translation unit, it issues an error message. Note that you can define functions outside the translation unit, even if you do not specify the RETURNCODE keyword.

- **OS_DOWNSTACK**
  Designates `identifier` as an OS linkage entry point in XPLINK mode with a downward growing stack frame.

  If the function identified by `identifier` is defined within the translation unit and is compiled using the NOXPLINK option, the compiler issues an error message.
OS_UPSTACK
Designates identifier as an OS linkage entry point in XPLINK mode with a traditional upward growing stack frame.

This linkage is required for a new XPLINK downward-stack routine to be able to call a traditional upward-stack OS routine. This linkage explicitly invokes compatibility code to swap the stack between the calling and the called routines.

If the function identified by identifier is defined within the translation unit and is compiled using the XPLINK option, the compiler issues an error message. Typically, the identifier will not be defined in a compilation. This is acceptable. In this case, it is a reference to an external procedure that is separately compiled with NOXPLINK.

OS_NOSTACK
Designates identifier as an OS linkage entry point in XPLINK mode with no preallocated stack frame. An argument list is constructed containing the addresses of the actual arguments. The size of the address is 4-byte for 31-bit and 8-byte for 64-bit. Register 1 is set to point to this argument list. For 31-bit only, the last item in this list has its high order bit set. For integer type arguments, the value passed is widened to the size of the long type, that is 4-byte for 31-bit and 8-byte for 64-bit. Register 13 points to a save area that may not be followed by z/OS Language Environment control structures, such as the NAB. The size of the save area is 72-byte for 31-bit and 144-byte for 64-bit. Register 14 contains the return address. Register 15 contains the entry point of the called function.

OS31_NOSTACK
This is synonymous with OS_NOSTACK for 64-bit with the exception that for 1, 2, and 4 byte integers the value is only widened to the size of an int.

REFERENCE
This is synonymous with OS_UPSTACK in non-XPLINK mode and synonymous with OS_DOWNSTACK in XPLINK mode. Unlike the linkage OS, this is not affected by the OSCALL suboption of XPLINK. Consider using this option instead to make the source code portable between XPLINK and non-XPLINK.

Usage
You can use a typedef in a #pragma linkage directive to associate a specific linkage convention with a function type. In the following example, the directive associates the OS linkage convention with the typedef func_t:

```c
typedef void func_t(void);
#pragma linkage (func_t,OS)
```

This typedef can then be used in C declarations wherever a function should have OS linkage. In the following example:

```c
func_t myfunction;
```

myfunction is declared as having type func_t, which is associated with OS linkage; myfunction would therefore have OS linkage.

Related information
- The XPLINK option in the z/OS XL C/C++ User's Guide.

#pragma longname/nolongname

Category

“Object code control” on page 416
Purpose
Specifies whether the compiler is to generate mixed-case names that can be longer than 8 characters in the object module.

Syntax
```
#pragma longname
#pragma nolongname
```

Defaults
- **C** noLongname
- **C++** longname

Parameters
- **longname**
The compiler generates mixed-case names in the object module. Names can be up to 1024 characters in length.

- **nolongname**
The compiler generates truncated and uppercase names in the object module. **C++** Only functions that do not have C++ linkage are given truncated and uppercase names.

Usage
If you use the `#pragma longname` directive, you must either use the binder to produce a program object in a PDSE, or you must use the prelinker. The binder, IPA link step, and prelinker support the long name directory that is generated by the Object Library utility for autocall.

If you specify the NOLONGNAME or LONGNAME compiler option, the compiler ignores the `#pragma longname` directive. If you specify either `#pragma nolongname` or the NOLONGNAME compiler option, and this results in mapping of two different source code names to the same object code name, the compiler will not issue an error message.

**C** If you have more than one preprocessor directive, `#pragma longname` may be preceded only by `#pragma filetag`, `#pragma chars`, `#pragma langlvl`, and `#pragma target`. Some directives, such as `#pragma variable` and `#pragma linkage`, are sensitive to the name handling.

**C++** You must specify `#pragma longname/nolongname` before any code. Otherwise, the compiler issues a warning message. `#pragma nolongname` must also precede any other preprocessing directive.

IPA effects
You must specify either the LONGNAME compile option or the `#pragma longname` preprocessor directive for the IPA compile step (unless you are using the c89 or cc utility from z/OS UNIX System Services, both of which already specify the LONGNAME compiler option). Otherwise, you will receive an unrecoverable compiler error.

Related information
- [“#pragma map” on page 447](#pragma_map)
#pragma map

**Category**
Object code control

**Purpose**
Converts all references to an identifier to another, externally defined identifier.

**Syntax**

```c
#pragma map syntax – C
```  
```c
#pragma map (name1, "name2")
```  

```c
#pragma map syntax – C++
```  
```c
#pragma map (name1(argument_list), "name2")
```  

**Parameters**

- **name1**
  
  The name used in the source code.  
  - **C** name1 can represent a data object or function with external linkage.  
  - **C++** name1 can represent a data object, a non-overloaded or overloaded function, or overloaded operator, with external linkage. If the name to be mapped is not in the global namespace, it must be fully qualified.  
  
  name1 should be declared in the same compilation unit in which it is referenced, but should not be defined in any other compilation unit. name1 must not be used in another #pragma map directive anywhere in the program.

- **argument_list**
  
  The list of arguments for the overloaded function or operator function designated by name1. If name1 designates an overloaded function, the function must be parenthesized and must include its argument list if it exists. If name1 designates a non-overloaded function, only name1 is required, and the parentheses and argument list are optional.

- **name2**
  
  The name that will appear in the object code.  
  - **C** name2 can represent a data object or function with external linkage. The compiler preserves mixed-case names. If the name is longer than 8 characters, you must use the binder and specify the LONGNAME compiler option.  
  - **C++** name2 can represent a data object, a non-overloaded or overloaded function, or overloaded operator, with external linkage. If the name is longer than 8 characters you must use the binder. name2 must be specified using its mangled name. To obtain C++ mangled names, compile your source to object files only, using the -c compiler option, and use the nm operating system command on the resulting object file.  
  
  If the name exceeds 65535 bytes, an informational message is emitted and the pragma is ignored. name2 may or may not be declared in the same compilation unit in which name1 is referenced, but must not be defined in the same compilation unit. Also, name2 should not be referenced anywhere in the compilation unit where name1 is referenced. name2 must not be the same as that used in another #pragma map directive or #pragma csect directive in the same compilation unit. The map name is not affected by the CONVLIT or the ASCII compiler options.
Usage

The `#pragma map` directive can appear anywhere in the program. Note that in order for a function to be actually mapped, the map target function (`name2`) must have a definition available at link time (from another compilation unit), and the map source function (`name1`) must be called in your program.

```c++
#pragma map
```

will look at the declarations prior to it and if satisfied will map the declaration. If it is not satisfied, it will check all declarations at the end of the compilation to see if it can find a match.

You cannot use `#pragma map` with compiler built-in functions.

Examples

The following is an example of `#pragma map` used to map a function name (using the mangled name for the map name in C++):

```c
/* Compilation unit 1: */
#include <stdio.h>
void foo();
extern void bar(); /* optional */
#if __cplusplus
#pragma map (foo, "bar__Fv")
#else
#pragma map (foo, "bar")
#endif
int main()
{
    foo();
}
/* Compilation unit 2: */
#include <stdio.h>
void bar()
{
    printf("Hello from foo bar!\n");
}
```

The call to `foo` in compilation unit 1 resolves to a call to `bar`:
Hello from foo bar!

`#pragma margins`

Category

"Language element control" on page 414

Purpose

Specifies the columns in the input line to scan for input to the compiler.

Syntax

```c
#include "stdio.h"
void foo();
extern void bar(); /* optional */
#if __cplusplus
#pragma map (foo, "bar__Fv")
#else
#pragma map (foo, "bar")
#endif
int main()
{
    foo();
}
/* Compilation unit 2: */
#include "stdio.h"
void bar()
{
    printf("Hello from foo bar!\n");
}
```

The call to `foo` in compilation unit 1 resolves to a call to `bar`:
Hello from foo bar!
Defaults

- margins(1,72) for fixed-length records. nomargins for variable-length records.
- nomargins for all records.

Parameters

margins
Specifies that only text within a range of margins, specified by first_column and last_column, is to be scanned by the compiler. The compiler ignores any text in the source input that does not fall within the range.

Specifying margins with no parameters is equivalent to margins(1,72) for both fixed or variable length records.

nomargins
Specifies that all input is to be scanned by the compiler.

first_column
A number representing the first column of the source input to be scanned. The value of first_column must be greater than 0, less than 32761, and less than or equal to the value of last_column.

last_column
A number representing the last column of the source input to be scanned. The value of last_column must be greater than the value of first_column, and less than 32761.

You can also use an asterisk (*) to indicate the last column of the input record. For example, if you specify #pragma margins (8, *), the compiler scans from column 8 to the end of input record.

Usage

The pragmas override the MARGINS or NOMARGINS compiler options. The setting specified by the #pragma margins directive applies only to the source file or include file in which it is found. It has no effect on other include files.

You can use #pragma margins and #pragma sequence together. If they reserve the same columns, #pragma sequence has priority and it reserves the columns for sequence numbers. For example, assume columns 1 to 20 are reserved for the margin, and columns 15 to 25 are reserved for sequence numbers. In this case, the margin will be from column 1 to 14, and the columns reserved for sequence numbers will be from 15 to 25.

Related information

- "#pragma sequence" on page 469

#pragma namemangling (C++ only)

Category

"Portability and migration" on page 417

Purpose

Chooses the name mangling scheme for external symbol names generated from C++ source code.

Syntax
Defaults

See the NAMEMANGLING option in the z/OS XL C/C++ User’s Guide.

By default, the maximum length of external symbol names (num_chars) is set as follows:

- 32767 — under ansi, zosv1r12_ansi, zosv1r11_ansi, zosv1r10_ansi, zosv1r9_ansi, zosv1r8_ansi, zosv1r7_ansi, or zosv1r5_ansi.
- 1024 — under zosv1r2 or zosv1r5_default.
- 255 — under compat or osv2r10.

Parameters

ansi
Indicates that the name mangling scheme complies with the most recent C++ language features. This setting is equivalent to zosv1r12_ansi. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r12_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 12 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r11_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 11 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r10_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 10 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r9_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 9 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r8_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 8 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r7_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 7 that were created with the #pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.
created with the \#pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r5_ansi
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 5 that were created with the \#pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 32767 characters, which is the maximum.

zosv1r5_default
Use this scheme for compatibility with link modules from z/OS C++ Version 1 Release 5 that were created with the default mangling for that compiler. This suboption uses the same name mangling scheme as modules created with z/OS C++ Version 1 Release 2 that were created with the \#pragma namemangling(ansi) directive or with the NAMEMANGLING(ANSI) compiler option in effect. The default value for num_chars is 1024 characters, which is the maximum.

zosv1r2
Same semantics as the zosv1r5_default suboption: instructs the compiler that the name mangling scheme is compatible with z/OS V1R2 link modules that were created with NAMEMANGLING(ANSI).

osv2r10
Use this scheme for compatibility with link modules created with the IBM OS/390 C++ Version 2 Release 10 compiler or earlier versions, or with link modules that were created with the \#pragma namemangling(compat) directive or with the NAMEMANGLING(COMPAT) compiler option in effect. The default value for num_chars is 255 characters, which is the maximum.

compat
Same semantics as the osv2r10 suboption: instructs the compiler that the name mangling scheme is compatible with that in OS/390 V2R10 and earlier versions.

num_chars
Represents a maximum for the length of the mangled name.

pop
Restores the name mangling scheme to that which was in effect immediately before the current setting. If no previous name mangling scheme was specified in the file, the scheme specified by the NAMEMANGLING compiler option is used.

Usage
For every \#pragma namemangling directive in your program, it is good practice to have a corresponding \#pragma namemangling(pop) as well. In this way, it is possible to prevent one file from potentially changing the name mangling setting of another file that is included.

Related information
• “\#pragma namemanglingrule (C++ only)”
• The NAMEMANGLING option in the z/OS XL C/C++ User’s Guide.

\#pragma namemanglingrule (C++ only)
Category
Portability and migration

Purpose
Provides fined-grained control over the name mangling scheme in effect for selected portions of source code, specifically with respect to the mangling of cv-qualifiers in function parameters.
When a function name is mangled, repeated function arguments of the same type are encoded according to the following compression scheme:

\[ \text{parameter } \rightarrow \text{T param number } \_ \text{ #single repeat of a previous parameter} \]
\[ \rightarrow \text{N repetition digit param number } \_ \text{ #2 to 9 repetitions} \]

where:

\textit{param number}

Indicates the number of the previous parameter which is repeated. It is followed by an underscore (_ ) if \textit{param number} contains multiple digits.

\textit{repetition digit}

Must be greater than 1 and less than 10. If an argument is repeated more than 9 times, this rule is applied multiple times. For example, a sequence of 38 parameters that are the same as parameter 1 mangles to N91N91N91N91N21.

The \texttt{#pragma namemanglingrule} directive allows you to control whether top-level cv-qualifiers are mangled in function parameters.

\textbf{Syntax}

```
# pragma namemanglingrule ( fnparmtype , off )
```

\textbf{Defaults}

- \texttt{fnparmtype, on} when the \texttt{#pragma namemangling(ansi)} directive or the NAMEMANGLING(ANSI) compiler option is in effect. Otherwise the default is \texttt{fnparmtype,off}.
- \texttt{fnparmscmp, on} when the \texttt{#pragma namemangling(ansi)} directive or the NAMEMANGLING(ANSI) compiler option is in effect. Otherwise the default is \texttt{fnparmscmp,off}.
- \texttt{fnparmstypedefscmp}, accepted both on AIX and z/OS, but has an effect on AIX only.

\textbf{Parameters}

\texttt{fnparmtype, on}

Top-level cv-qualifiers are not encoded in the mangled name of a function parameter. Also, top-level cv-qualifiers are ignored when repeated function parameters are compared for equivalence; function parameters that differ only by the use of a top-level cv-qualifier are considered equivalent and are mangled according to the compressed encoding scheme.

\texttt{fnparmtype, off}

Top-level cv-qualifiers are encoded in the mangled name of a function parameter. Also, repeated function parameters that differ by the use of cv-qualifiers are not considered equivalent and are mangled as separate parameters. This setting is compatible with z/OS C++ Version 1 Release 5.

\texttt{fnparmtype, pop}

Reverts to the previous \texttt{fnparmtype} setting in effect. If no previous settings are in effect, the default \texttt{fnparmtype} setting is used.

\textbf{Note}: This pragma fixes function signature ambiguities in 32-bit mode, but it is not needed in 64-bit mode since those ambiguities do not exist in 64-bit mode.
fnparmscmp, on
Intermediate-level cv-qualifiers are considered when repeated function parameters are compared for equivalence; repeated function parameters that differ by the use of intermediate-level cv-qualifiers are mangled as separate parameters.

fnparmscmp, off
Intermediate-level cv-qualifiers are ignored when repeated function parameters are compared for equivalence; function parameters that differ only by the use of an intermediate-level cv-qualifier are considered equivalent and are mangled according to the compressed encoding scheme. This setting is compatible with z/OS C++ Version 1 Release 5.

fnparmscmp, pop
Reverts to the previous fnparmscmp setting in effect. If no previous settings are in effect, the default fnparmscmp setting is used.

Usage

#pragma namemanglingrule is allowed in global, class, and function scopes. It has no effect on a block scope function declaration with external linkage.

Different pragma settings can be specified in front of function declarations and definitions. If #pragma namemanglingrule settings in subsequent declarations and definitions conflict, the compiler ignores those settings and issues a warning message.

Examples

The following table shows the effects of this pragma applied to different function signatures.

Table 39. Mangling of function parameters with top-level cv-qualifiers

<table>
<thead>
<tr>
<th>Source name</th>
<th>Mangled name</th>
<th>fnparmtype, off</th>
<th>fnparmtype, on</th>

- The NAMEMANGLING option in the z/OS XL C/C++ User's Guide.

#pragma object_model (C++ only)

Category

"Portability and migration" on page 417

Purpose

Sets the object model to be used for structures, unions, and classes.

The object models differ in the areas of layout for the virtual function table, support for virtual base classes, and name mangling scheme.

Syntax

```
#pragma object_model( ibm )
```

Defaults

The default is compat.

Parameters

- **compat**
  - Is compatible with name mangling and the virtual function table that was available with the previous releases of the z/OS C++ compiler.

- **ibm**
  - Provides improved performance. Class hierarchies with many virtual base classes can benefit from this option because the size of the derived class is smaller and access to the virtual function table is faster. You must use XPLINK when specifying this option.

- **pop**
  - Sets the object model setting to that which was in effect before the current setting.

Usage

Classes implicitly inherit the object model of their parent, overriding any local object model specification. All classes in the same inheritance hierarchy must have the same object model. An error is generated if, through multiple inheritance, the object models for base classes are mixed.

Examples

The following example illustrates how the inheritance mechanism supersedes the #pragma object_model specification.

```
#pragma object_model(ibm)
class A{}; // ibm model: pragma is used
#pragma object_model(compat)
class B: A{}; // ibm model: pragma is ignored because of // inheritance
            // (A is "ibm", therefore B is "ibm")
#pragma object_model(ibm)
class C: B{};  // ibm model: pragma is ignored because of
```

454  z/OS V1R13.0 XL C/C++ Language Reference
// inheritance
   // (B is "ibm", therefore C is "ibm")
#pragma object_model(compat)
class D{}; // compat model: no inheritance, pragma is used
class E: A, D{}; // ERROR: A and D have differing object models.
#pragma object_model(compat)
class F: B, C{}; // ibm model: pragma is ignored because of inheritance
   // (B and C are "ibm", therefore F is "ibm")
   // Same object model for the inheritance hierarchy

Related information
• The OBJECTMODEL option in the z/OS XL C/C++ User's Guide.

#pragma operator_new (C++ only)
Category
Error checking and debugging

Purpose
Determines whether the \texttt{new} and \texttt{new[]} operators throw an exception if the requested memory cannot be allocated.

This pragma is equivalent to the LANGLVL(NEWEXCP) option.

Syntax
\begin{verbatim}
# pragma operator_new ( \texttt{returnsnull} )
# pragma operator_new ( \texttt{throwexception} )
\end{verbatim}

Defaults
\texttt{returnsnull}

Parameters
\begin{itemize}
\item \texttt{returnsnull} 
  If the memory requested by the \texttt{new} operator cannot be allocated, the compiler returns 0, the null pointer. Use this option for compatibility with versions of the XL C++ compiler previous to V1R7.
\item \texttt{throwexception} 
  If the memory requested by the \texttt{new} operator cannot be allocated, the compiler throws a standard exception of type \texttt{std::bad_alloc}. Use this option in new applications, for conformance with the C++ standard.
\end{itemize}

Usage
The pragma can be specified only once in a source file. It must appear before any statements in the source file. This pragma takes precedence over the LANGLVL(NEWEXCP) compiler option.

Restrictions
This pragma applies only to versions of the \texttt{new} operator that throw exceptions; it does not apply to the \texttt{nothrow} or empty \texttt{throw} versions of the \texttt{new} operator (for the prototypes of all the \texttt{new} operator versions, see the description of the \texttt{<new>} header in the Standard C++ Library Reference). It also does not apply to
class-specific new operators, user-defined new operators, and new operators with placement arguments.

Related information
- "new expressions (C++ only)" on page 153
- "Allocation and deallocation functions (C++ only)" on page 214
- The LANGLVL compiler option in the z/OS XL C/C++ User’s Guide.

#pragma option_override

Category

Optimization and tuning

Purpose

Allows you to specify optimization options at the subprogram level that override optimization options given on the command line.

This enables finer control of program optimization, and can help debug errors that occur only under optimization.

Syntax

```plaintext
#pragma option_override (identifier, "opt ( compact )")
```

Parameters

**identifier**

The name of a function for which optimization options are to be overridden.

The following table shows the equivalent command line option for each pragma suboption.

<table>
<thead>
<tr>
<th>#pragma option_override value</th>
<th>Equivalent compiler option</th>
</tr>
</thead>
<tbody>
<tr>
<td>compact</td>
<td>COMPACT</td>
</tr>
<tr>
<td>compact, yes</td>
<td>NOCOMPACT</td>
</tr>
<tr>
<td>level, 0</td>
<td>OPT(0)</td>
</tr>
<tr>
<td>level, 1</td>
<td>OPT(1)</td>
</tr>
<tr>
<td>level, 2</td>
<td>OPT(2)</td>
</tr>
<tr>
<td>level, 3</td>
<td>OPT(3)</td>
</tr>
<tr>
<td>spill, size</td>
<td>SPILL(size)</td>
</tr>
<tr>
<td>strict</td>
<td>STRICT</td>
</tr>
</tbody>
</table>
#pragma option_override value | Equivalent compiler option
---|---
strict, no | NO STRICT

 Defaults

See the descriptions in the *z/OS XL C/C++ User's Guide* for the options listed in the table above for default settings.

 Usage

The pragma takes effect only if optimization is already enabled by a command-line option. You can only specify an optimization level in the pragma _lower_ than the level applied to the rest of the program being compiled.

The **#pragma option_override** directive only affects functions that are defined in the same compilation unit. The pragma directive can appear anywhere in the translation unit. That is, it can appear before or after the function definition, before or after the function declaration, before or after the function has been referenced, and inside or outside the function definition.

This pragma cannot be used with overloaded member functions.

 Examples

Suppose you compile the following code fragment containing the functions foo and faa using OPT(1). Since it contains the **#pragma option_override(faa, "opt(level, 0)")**, function faa will not be optimized.

```c
foo(){
   .
   .
   .
}

#pragma option_override(faa, "opt(level, 0)")

faa(){
   .
   .
   .
}
```

 IPA effects

You cannot specify the IPA compiler option for **#pragma option_override**.

During IPA compile processing, subprogram-specific options will be used to control IPA compile-time optimizations.

During IPA link processing, subprogram-specific options will be used to control IPA link-time optimizations, as well as program partitioning. They will be retained, even if the related IPA link command line option is specified.

 Related information

- The OPT, COMPACT, SPILL and STRICT options in the *z/OS XL C/C++ User's Guide*. 
#pragma options (C only)

Category

"Language element control" on page 414

Purpose

Specifies a list of compiler options that are to be processed as if you had typed them on the command line or on the CPARM parameter of the IBM-supplied catalogued procedures.

Syntax

```
#pragma options ( aggregate )
```

- `aggregate`
- `noaggregate`
- `alias`
- `noalias`
- `ansialias`
- `noansialias`
- `architecture`
- `checkout`
- `nocheckout`
- `gonumber`
- `nogonumber`
- `ignerrno`
- `noignerrno`
- `inline`
- `noinline`
- `libansi`
- `nolibansi`
- `maxmem`
- `nomaxmem`
- `object`
- `noobject`
- `optimize`
- `nooptimize`
- `rent`
- `norent`
- `service`
- `moservice`
- `spill`
- `nospill`
- `start`
- `nostart`
- `test`
- `notest`
- `tune`
- `upconv`
- `noupconv`
- `xref`
- `noxref`

Defaults

See the z/OS XL C/C++ User's Guide for the default settings for these options.
Parameters
See the z/OS XL C/C++ User's Guide for descriptions of these options.

Usage
If you use a compile option that contradicts the options that are specified on the #pragma options directive, the compiler option overrides the options on the #pragma options directive.

If you specify an option more than once, the compiler uses the last one you specified.

IPA effects
You cannot specify the IPA compiler option for #pragma options.

Related information
• z/OS XL C/C++ User's Guide
• For a detailed description of the interaction between the INLINE compiler option on the invocation line and the #pragma options preprocessor directive, see the INLINE compiler option description in the z/OS XL C/C++ User's Guide.

#pragma pack
Category
Object code control

Purpose
Sets the alignment of all aggregate members to a specified byte boundary.

If the byte boundary number is smaller than the natural alignment of a member, padding bytes are removed, thereby reducing the overall structure or union size.

Syntax
```
#pragma pack (number)
```

Defaults
Members of aggregates (structures, unions, and classes) are aligned on their natural boundaries and a structure ends on its natural boundary. The alignment of an aggregate is that of its strictest member (the member with the largest alignment requirement).

Parameters

number is one of the following:

1 Aligns structure members on 1-byte boundaries, or on their natural alignment boundary, whichever is less.
Aligns structure members on 2-byte boundaries, or on their natural alignment boundary, whichever is less.

Aligns structure members on 4-byte boundaries, or on their natural alignment boundary, whichever is less.

Reserved for possible future use.

Reserved for possible future use.

Aligns structure members on 4-byte boundaries, or on their natural alignment boundary, whichever is less. This is the same as #pragma pack() and #pragma pack(4).

num:C_Compat

num is one of the following:

- 1 (aligns structure members on 1-byte boundaries, or on their natural alignment boundary, whichever is less)
- 2 (aligns structure members on 2-byte boundaries, or on their natural alignment boundary, whichever is less)

num:C_Compat aligns structure members so that the class layout will be compatible with the layout produced by the XL C compiler. This applies when:

- You have a class layout that is guarded by #pragma pack(1) or #pragma pack(2).
- Your class data member contains a bit field that has an alignment that exceeds the alignment defined by #pragma pack(1) or #pragma pack(2).
- The bit length of the bit field exceeds the maximum number that the bit field type is allowed to contain.

Aligns structure members on 1-byte boundaries, or on their natural alignment boundary, whichever is less. This is the same as #pragma pack(1).

Aligns structure members on 2-byte boundaries, or on their natural alignment boundary, whichever is less. This is the same as #pragma pack(2).

Sets the packing rule to that which was in effect before the current setting.

Usage

The #pragma pack directive applies to the definition of an aggregate type, rather than to the declaration of an instance of that type; it therefore automatically applies to all variables declared of the specified type.

The #pragma pack directive modifies the current alignment rule for only the members of structures whose declarations follow the directive. It does not affect the alignment of the structure directly, but by affecting the alignment of the members of the structure, it may affect the alignment of the overall structure.

The #pragma pack directive cannot increase the alignment of a member, but rather can decrease the alignment. For example, for a member with data type of short, a #pragma pack(1) directive would cause that member to be packed in the structure on a 1-byte boundary, while a #pragma pack(4) directive would have no effect.

The #pragma pack directive applies only to complete declarations of structures or unions; this excludes forward declarations, in which member lists are not specified. For example, in the following code fragment, the alignment for struct S is 4, since this is the rule in effect when the member list is declared:
#pragma pack(1)
struct S;
#pragma pack(4)
struct S { int i, j, k; };

A nested structure has the alignment that precedes its declaration, not the alignment of the structure in which it is contained, as shown in the following example:

```
#pragma pack (4)  // 4-byte alignment
struct nested {
    int x;
    char y;
    int z;
};
#pragma pack(1)   // 1-byte alignment
struct packedcxx{ char a;
    short b;
    struct nested s1;  // 4-byte alignment
};
```

If more than one #pragma pack directive appears in a structure defined in an inlined function, the #pragma pack directive in effect at the beginning of the structure takes precedence.

**Examples**

The following example shows how the #pragma pack directive can be used to set the alignment of a structure definition:

```
// header file file.h
#pragma pack(1)
struct jeff{  // this structure is packed
    short bill;  // along 1-byte boundaries
    int *chris;
};
#pragma pack(reset) // reset to previous alignment rule
// source file anyfile.c
#include "file.h"
struct jeff j;  // uses the alignment specified
    // by the pragma pack directive
    // in the header file and is
    // packed along 1-byte boundaries
```

This example shows how a #pragma pack directive can affect the size and mapping of a structure:

```
struct s_t {
    char a;
    int b;
    short c;
    int d;
}S;
```

**Default mapping:**

- size of s_t = 16
- offset of a = 0
- offset of b = 4
- offset of c = 8
- offset of d = 12

**With #pragma pack(1):**

- size of s_t = 11
- offset of a = 0
- offset of b = 1
- offset of c = 5
- offset of d = 7
**Default mapping:**

- alignment of \( a = 1 \)
- alignment of \( b = 4 \)
- alignment of \( c = 2 \)
- alignment of \( d = 4 \)

**With \#pragma pack(1):**

- alignment of \( a = 1 \)
- alignment of \( b = 1 \)
- alignment of \( c = 1 \)
- alignment of \( d = 1 \)

The following example defines a union \( uu \) containing a structure as one of its members, and declares an array of 2 unions of type \( uu \):

```c
union uu {
    short a;
    struct {
        char x;
        char y;
        char z;
    } b;
};
union uu nonpacked[2];
```

Since the largest alignment requirement among the union members is that of short \( a \), namely, 2 bytes, one byte of padding is added at the end of each union in the array to enforce this requirement:

```
+-------------------+-------------------+
|  nonpacked[0]    |  nonpacked[1]    |
|    │a│ │a│ │    |
|    │x│y│z│ │x│y│z│ |
+-------------------+-------------------+
```

The next example uses \#pragma pack(1) to set the alignment of unions of type \( uu \) to 1 byte:

```
#pragma pack(1)
union uu {
    short a;
    struct {
        char x;
        char y;
        char z;
    } b;
};
union uu pack_array[2];
```

Now, each union in the array packed has a length of only 3 bytes, as opposed to the 4 bytes of the previous case:

```
+-------------------+-------------------+
|  packed[0]    |  packed[1]    |
|    │a│ │a│ │    |
|    │x│y│z│ │x│y│z│ |
+-------------------+-------------------+
```
#pragma page (C only)

**Category**

“Listings, messages and compiler information” on page 415

**Purpose**

Specifies that the code following the pragma begins at the top of the page in the generated source listing.

**Syntax**

```
#pragma page(number)
```

**Defaults**

Not applicable.

**Parameters**

`number`

The number of pages from the current page on which to begin writing the line of source code that follows the pragma. #pragma page() is the same as #pragma page(1); the source line that follows the pragma will start on a new page. If you specify #pragma page(2), the listing will skip one blank page and the source line following the pragma will start on the second page after the current page. In all cases, the listing continues.

#pragma pagesize (C only)

**Category**

“Listings, messages and compiler information” on page 415

**Purpose**

Sets the number of lines per page for the generated source listing.

**Syntax**

```
#pragma pagesize(number)
```

**Defaults**

The default page size is 66 lines.

**Parameters**

`number`

The number of lines per page for the generated source listing.

**Usage**

The minimum page size that you should set is 25.
IPA effects

This pragma has the same effect on the IPA compile step as it does on a regular compilation. It has no effect on the IPA link step.

### #pragma priority (C++ only)

#### Category

Object code control

#### Purpose

Specifies the priority level for the initialization of static objects.

The C++ standard requires that all global objects within the same translation unit be constructed from top to bottom, but it does not impose an ordering for objects declared in different translation units. The #pragma priority directive allows you to impose a construction order for all static objects declared within the same load module. Destructors for these objects are run in reverse order during termination.

#### Syntax

Pragma syntax

```
# pragma priority (<number>)
```

#### Defaults

The default priority level is 0.

#### Parameters

**number**

An integer literal in the range of -2,147,482,624 to 2,147,483,647. A lower value indicates a higher priority; a higher value indicates a lower priority. Numbers from -2,147,836,488 to -2,147,826,234 are reserved for system use. If you do not specify a number, the compiler assumes 0.

#### Usage

More than one #pragma priority can be specified within a translation unit. The priority value specified in one pragma applies to the constructions of all global objects declared after this pragma and before the next one. However, in order to be consistent with the Standard, priority values specified within the same translation unit must be strictly increasing. Objects with the same priority value are constructed in declaration order.

The effect of a #pragma priority exists only within one load module. Therefore, #pragma priority cannot be used to control the construction order of objects in different load modules. Refer to z/OS XL C/C++ Programming Guide for further discussions on techniques used in handling DLL static object initialization.

### #pragma prolog (C only), #pragma epilog (C only)

#### Category

Object code control on page 416
Purpose

When used with the METAL option, inserts High-Level Assembly (HLASM) prolog or epilog code for a specified function.

Prologs are inserted after function entry, and epiloggs are inserted before function return in the generated HLASM code. These directives allow you to provide your own function entry and exit code for system programming.

Syntax

```
#pragma epilog (function_name, "HLASM Statements")

#pragma prolog (function_name, main)
```

Starting from z/OS V1R11, the following syntax is also supported:

```
#pragma epilog (function_name, main)

#pragma prolog (function_name, "HLASM Statements")
```

Defaults

Not applicable.

Parameters

`function_name`

The name of a function to which the epilog or prolog is to be inserted in the generated HLASM code.

`HLASM Statements`

`HLASM Statements` is a C string, which must contain valid HLASM statements. If the `HLASM Statements` consists of white-space characters only, or if the `HLASM Statements` is not provided, then the compiler ignores the option specification. If the `HLASM Statements` does not contain any white-space characters, then the compiler will insert leading spaces in front. Otherwise, the compiler will insert the `HLASM Statements` into the function prolog location of the generated assembler source. The compiler does not understand or validate the contents of the `HLASM Statements`. In order to satisfy the assembly step later, the given `HLASM Statements` must form valid HLASM code with the surrounding code generated by the compiler.

Note: Special characters like `newline` and `quote` are shell (or command line) meta characters, and maybe preprocessed before reaching the compiler. It is advisable to avoid using them.

`main`

When the keyword `main` is specified instead of `HLASM Statements`, the default prolog/epilog code generated by the compiler for `function_name` is the same as if it was generated for function `main`.

Usage

If a `#pragma prolog/epilog` directive is specified, the pragma directive overrides its respective compiler option.

An HLASM macro name, or any HLASM statements can be specified in the string parameter. Normal programming language (C/C++) rules for string literals apply to the string arguments of the pragma directives as well as to the compiler options.

These directives are only recognized when the z/OS XL C METAL compiler option is in effect.

Only one `#pragma epilog` or `#pragma prolog` directive is allowed for a specific function.
Related information
- EPILOG, PROLOG, and METAL options in the z/OS XL C/C++ User's Guide.
- Default prolog and epilog code information in the z/OS Metal C Programming Guide and Reference.

#pragma reachable

Category
Optimization and tuning

Purpose
Informs the compiler that the point in the program after a named function can be the target of a branch from some unknown location.

By informing the compiler that the instruction after the specified function can be reached from a point in your program other than the return statement in the named function, the pragma allows for additional opportunities for optimization.

Syntax
```
#pragma reachable(function_name)
```

Parameters

function_name
The name of a function preceding the instruction which is reachable from a point in the program other than the function's return statement.

Defaults
Not applicable.

Usage
Unlike the #pragma leaves, #pragma reachable is required by the compiler optimizer whenever the instruction following the call may receive control from some program point other than the return statement of the called function. If this condition is true and #pragma reachable is not specified, then the subprogram containing the call should not be compiled with OPT(1), OPT(2), OPT(3), or IPA. See also "#pragma leaves" on page 442.

If you specify the LIBANSI compiler option (which informs the compiler that function names that match functions in the C standard library are in fact C library functions), the compiler checks whether the setjmp family of functions (setjmp, _setjmp, sigsetjmp, and _sigsetjmp) contain #pragma reachable. If the functions do not contain this pragma directive, the compiler will insert this directive for the functions. This is not shown in the listing.

IPA effects
If you specify the #pragma reachable directive in your source code in the IPA compile step, you cannot override the effects of this directive in the IPA link step.

If you specify the LIBANSI compile option for any translation unit in the IPA compile step, the compiler generates information which indicates the setjmp family of functions contain the reachable status. If you specify the NOLIBANSI option for the IPA link step, the attribute remains in effect.
Related information

- 

#pragma leaves" on page 442

#pragma report (C++ only)

Category

Listings, messages and compiler information

Purpose

Controls the generation of diagnostic messages.

The pragma allows you to specify a minimum severity level for a message for it to display, or allows you to enable or disable a specific message regardless of the prevailing report level.

Syntax

```
#pragma report ( level, E )
```

Defaults

The default report level is Informational (I), which displays messages of all types.

Parameters

level

Indicates that the pragma is set according to the minimum severity level of diagnostic messages to display.

E

Indicates that only error messages will display. Error messages are of the highest severity. This is equivalent to the FLAG(E) compiler option.

W

Indicates that warning and error messages will display. This is equivalent to the FLAG(W) compiler option.

I

Indicates that all diagnostic messages will display: warning, error and informational messages. Informational messages are of the lowest severity. This is equivalent to the FLAG(I) compiler option.

enable

Enables the specified "message_number".

disable

Disables the specified "message_number".

"message_number"

Represents a message identifier, which consists of a prefix followed by the message number in quotation marks; for example, "CCN1004".

Note: You must use quotation marks with message_number as in the preceding example “CCN1004”.

pop

Reverts the report level to that which was previously in effect. If no previous report level has been specified, a warning is issued, and the report level remains unchanged.
Usage

The pragma takes precedence over most compiler options. For example, if you use `#pragma report` to disable a compiler message, that message will not be displayed with any FLAG compiler option setting. Similarly, if you specify the SUPPRESS compiler option for a message but also specify `#pragma report(enable)` for the same message, the pragma will prevail.

Related information
- The FLAG option in the z/OS XL C/C++ User's Guide.

`#pragma runopts`

Category

"Language element control" on page 414

Purpose

Specifies a list of runtime options for the compiler to use at execution time.

Syntax

```
#pragma runopts(suboption)
```

Defaults

Not applicable.

Parameters

suboption

A z/OS Language Environment run-time option or any of the compiler run-time options ARGPARSE, ENV, PLIST, REDIR, or EXECOPS. For more information on z/OS run-time options, see the z/OS XL C/C++ User's Guide and z/OS Language Environment Programming Guide.

Usage

Specify your `#pragma runopts` directive in the translation unit that contains `main`. If more than one translation unit contains a `#pragma runopts` directive, unpredictable results can occur; the `#pragma runopts` directive only affects translation units containing `main`.

If a suboption to `#pragma runopts` is not a valid C or C++ token, you can surround the suboptions to `#pragma runopts` in double quotes. For example, use:

```
#pragma runopts ("RPTSTG(ON) TEST(,,VADTCPIP&1.2.3.4:*)"
```

instead of:

```
#pragma runopts (RPTSTG(ON) TEST(,,VADTCPIP&1.2.4.3:*)
```

IPA effects

This pragma only affects the IPA compile step if you specify the OBJECT suboption of the IPA compiler option.
The IPA compile step passes the effects of this directive to the IPA link step.

Consider if you specify ARGPARSE|NOARGPARSE, EXECOPS|NOEXECOPS, PLIST, or REDIR|NOREDIR either on the `#pragma runopts` directive or as a compile-time option on the IPA compile step, and then specify the compile-time option on the IPA link step. In this case, you override the value that you specified on the IPA compile step.

If you specify the TARGET compile-time option on the IPA link step, it has the following effects on `#pragma runopts`:

- It overrides the value you specified for `#pragma runopts(ENV)`. If you specify TARGET(LE) or TARGET(), the compiler sets the value of `#pragma runopts(ENV)` to MVS. If you specify TARGET(IMS), the compiler sets the value of `#pragma runopts(ENV)` to IMS.
- It may override the value you specified for `#pragma runopts(PLIST)`. If you specify TARGET(LE) or TARGET(), and you specified something other than HOST for `#pragma runopts(PLIST)`, the compiler sets the value of `#pragma runopts(PLIST)` to HOST. If you specify TARGET(IMS), the compiler sets the value of `#pragma runopts(PLIST)` to IMS.

For `#pragma runopts` options other than those that are listed above, the IPA link step follows these steps to determine which `#pragma runopts` value to use:

1. The IPA link step uses the `#pragma runopts` specification from the main routine, if the routine exists.
2. If no main routine exists, the IPA link step follows these steps:
   a. If you define the CEEUOPT variable, the IPA link step uses the `#pragma runopts` value from the first translation unit that it finds that contains CEEUOPT.
   b. If you have not defined the CEEUOPT variable in any translation unit, the IPA link step uses the `#pragma runopts` value from the first translation unit that it processes.

The sequence of translation unit processing is arbitrary.

To avoid problems, you should specify `#pragma runopts` only in your main routine. If you do not have a main routine, specify it in only one other module.

Related information
- "#pragma target (C only)" on page 472
- The TARGET option in the z/OS XL C/C++ User's Guide.

### #pragma sequence

**Category**

"Language element control" on page 414

**Purpose**

Defines the section of the input record that is to contain sequence numbers.

The `#pragma nosequence` directive specifies that the input record does not contain sequence numbers.

**Syntax**

```
#pragma sequence(--left_column_margin--,--right_column_margin--) nosequence
```
Defaults

- C Sequence numbers are assigned to columns 73 through 80 of the input record for fixed-length-records, and no sequence numbers are assigned for variable-length records. - C++ No sequence numbers are assigned for fixed or variable-length records.

Parameters

left_column_margin
The column number of the first (left-hand) margin. The value of left_column_margin must be greater than 0, and less than 32767.

Also, left_column_margin must be less than or equal to the value of right_column_margin.

right_column_margin
The column number of the last (right-hand) margin. The value of right_column_margin must be greater than that of left_column_margin, and less than 32767.

You can also use an asterisk (*) to indicate the last column of the input record. For example, sequence(74,*) indicates that sequence numbers are between column 74 and the end of the input record.

Usage

- C++ In C++ only, you can specify the sequence option with no parameters, which instructs the compiler to number columns 73 through 80 of the input record (fixed or variable length).

If you use the compiler options SEQUENCE or NOSEQUENCE with the #pragma sequence/nosequence directive, the directive overrides the compiler options. The compiler option is in effect up to the first #pragma sequence/nosequence directive. The sequence setting specified by the #pragma sequence directive applies only to the file (source file or include file) that contains it. The setting has no effect on other include files in the file.

You can use #pragma sequence and #pragma margins together. If they reserve the same columns, #pragma sequence has priority, and the compiler reserves the columns for sequence numbers. For example, consider if the columns reserved for the margin are 1 to 20 and the columns reserved for sequence numbers are 15 to 25. In this case, the margin will be from column 1 to 14, and the columns reserved for sequence numbers will be from 15 to 25. For more information on the #pragma margins directive, refer to "#pragma margins" on page 448.

Related information
- The SEQUENCE option in the z/OS XL C/C++ User's Guide.

#pragma skip (C only)
Category

Listing, messages and compiler information” on page 415

Purpose

Skips lines of the generated source listing.

Syntax

#pragma skip directive syntax
#pragma skip(number)

**Defaults**

Not applicable.

**Parameters**

`number`

The number of lines to skip in the generated source listing. The value of `number` must be a positive integer less than 255. If you omit `number`, the compiler skips one line.

### #pragma strings

**Category**

Object code control

**Purpose**

Specifies the storage type for string literals.

**Syntax**

Pragma syntax

```
#pragma strings(readonly | writable)
```

**Defaults**

C and C++ strings are read-only.

**Parameters**

`readonly`

String literals are to be placed in read-only memory.

`writeable`

String literals are to be placed in read-write memory.

**Usage**

Placing string literals in read-only memory can improve runtime performance and save storage. However, code that attempts to modify a read-only string literal may generate a memory error.

The pragma must appear before any source statements in a file.

**IPA effects**

During the IPA link step, the compiler compares the `#pragma strings` specifications for individual translation units. If it finds differences, it treats the strings as if you specified `#pragma strings(writeable)` for all translation units.
Related information
- The ROSTRINGS option in the z/OS XL C/C++ User's Guide.

#pragma subtitle (C only)

Category
"Listings, messages and compiler information" on page 415

Purpose
Places subtitle text on all subsequent pages of the generated source listing.

Syntax
```c
#pragma subtitle ("text")
```

Defaults
Not applicable.

Parameters
text
The subtitle to appear in on all pages of the generated source listing.

#pragma target (C only)

Category
"Object code control" on page 416

Purpose
Specifies the operating system or runtime environment for which the compiler creates the object module.

Syntax
```c
#pragma target (LE)
```

Defaults
The default is LE.

Parameters
LE
Generates code to run under the z/OS Language Environment run-time library. This is equivalent to specifying ```#pragma target()``` . This suboption has the following effects on ```#pragma runopts(ENV)``` and ```#pragma runopts(PLIST)```:
- If you did not specify values for ```#pragma runopts(ENV)``` or ```#pragma runopts(PLIST)``` , the compiler sets the pragmas to ```#pragma runopts(ENV(MVS))``` and ```#pragma runopts(PLIST(HOST))```.
- If you did specify values for ```#pragma runopts(ENV)``` or ```#pragma runopts(PLIST)``` , the values do not change.
IMS
Generates object code to run under IMS. This suboption has the following effects on `#pragma runopts(ENV)` and `#pragma runopts(PLIST)`:

- If you did not specify values for `#pragma runopts(ENV)` or `#pragma runopts(PLIST)`, the compiler sets the pragmas to `#pragma runopts(ENV(IMS))` and `#pragma runopts(PLIST(OS))`.
- If you did specify values for `#pragma runopts(ENV)` or `#pragma runopts(PLIST)`, the values do not change.

Usage
Note that you cannot specify the release suboptions using the `#pragma target` directive as you can with the TARGET compiler option.

The only pragma directives that can precede `#pragma target` are `filetag`, `chars`, `langlvl`, and `longname`.

IPA effects
This pragma only affects the IPA compile step if you specify the OBJECT suboption of the IPA compiler option.

The IPA compile step passes the effects of this pragma to the IPA link step.

If you specify different `#pragma target` directives for different translation units, the IPA link step uses the ENV and PLIST information from the translation unit containing `main`. If there is no `main`, it uses information from the first translation unit it finds. If you specify the TARGET compile option for the IPA link step, it overrules the `#pragma target` directive.

Related information
- `"#pragma runopts" on page 468`
- The TARGET option in the z/OS XL C/C++ User's Guide.

`#pragma title (C only)`

Category
"Listings, messages and compiler information" on page 415

Purpose
Places title text on all subsequent pages of the generated source listing.

Syntax
```
#pragma title("text")
```

Defaults
Not applicable.

Parameters
text
The title to appear in on all pages of the generated source listing.
#pragma unroll

Category
Optimization and tuning

Purpose
Controls loop unrolling, for improved performance.

When unroll is in effect, the optimizer determines and applies the best unrolling factor for each loop; in some cases, the loop control may be modified to avoid unnecessary branching. The compiler remains the final arbiter of whether the loop is actually unrolled.

Syntax
Pragma syntax
```
#pragma unroll(number)
```

Defaults
See the description of the UNROLL option in the z/OS XL C/C++ User's Guide.

Parameters
number
Forces number - 1 replications of the designated loop body or full unrolling of the loop, whichever occurs first. The value of number is unbounded and must be a positive integer. Specifying #pragma unroll(1) effectively disables loop unrolling, and is equivalent to specifying #pragma nounroll.

Usage
The pragma overrides the [NO]UNROLL compiler option setting for a designated loop. However, even if #pragma unroll is specified for a given loop, the compiler remains the final arbiter of whether the loop is actually unrolled.

Only one pragma may be specified on a loop. The pragma must appear immediately before the loop to have effect.

The pragma affects only the loop that follows it. An inner nested loop requires a #pragma unroll directive to precede it if the desired loop unrolling strategy is different from that of the prevailing [NO]UNROLL option.

The #pragma unroll and #pragma nounroll directives can only be used on for loops. They cannot be applied to do while and while loops.

The loop structure must meet the following conditions:
- There must be only one loop counter variable, one increment point for that variable, and one termination variable. These cannot be altered at any point in the loop nest.
- Loops cannot have multiple entry and exit points. The loop termination must be the only means to exit the loop.
- Dependencies in the loop must not be “backwards-looking”. For example, a statement such as A[i][j] = A[i -1][j +1] + 4) must not appear within the loop.
Predefined macros

None.

Examples

In the following example, the `#pragma unroll(3)` directive on the first `for` loop requires the compiler to replicate the body of the loop three times. The `#pragma unroll` on the second `for` loop allows the compiler to decide whether to perform unrolling.

```c
#pragma unroll(3)
for( i=0; i < n; i++)
{
    a[i] = b[i] * c[i];
}
#pragma unroll
for( j=0; j < n; j++)
{
    a[j] = b[j] * c[j];
}
```

In this example, the first `#pragma unroll(3)` directive results in:

```c
i=0;
if (i>n-2) goto remainder;
for (; i<n-2; i+=3) {
    a[i]=b[i] * c[i];
    a[i+1]=b[i+1] * c[i+1];
    a[i+2]=b[i+2] * c[i+2];
}
if (i<n) {
    remainder:
    for (; i<n; i++) {
        a[i]=b[i] * c[i];
    }
}
```

Related information

- The UNROLL option in the z/OS XL C/C++ User's Guide.

#pragma variable

Category

"Object code control" on page 416

Purpose

Specifies whether the compiler is to use a named external object in a reentrant or non-reentrant fashion.

Syntax

```c
#pragma variable( identifier, [rent|norent])
```

Defaults

- C++ Variables are reentrant (`rent`).  
- C Variables are not reentrant (`norent`).
Parameters

**identifier**

The name of an external variable.

**rent**

Specifies that the variable's references or definition will be in the writable static area that is in modifiable storage.

**norent**

Specifies that the variable's references or its definition is in the code area and is in potentially read-only storage. This suboption does not apply to, and has no effect on, program variables with static storage class.

Usage

If an identifier is defined in one translation unit and used in another, the reentrant or non-reentrant status of the variable must be the same in all translation units.

To specify that variables declared as const not be placed into the writeable static area, you must use the ROCONST and RENT compiler options.

If the specification for a const variable in a `#pragma variable` directive conflicts with the ROCONST option, the pragma directive takes precedence over the compiler option, and the compiler issues an informational message.

If you use the norent suboption for a variable, ensure that your program never writes to this variable. Program exceptions or unpredictable program behavior may result should this be the case.

The following code fragment leads to undefined behavior when compiled with the RENT option.

```c
int i;
int *p = &i;
#pragma variable(p, norent)
```

The variable i is reentrant, but the pointer p is non-reentrant. If the code is in a DLL, there will only be one copy of p but multiple copies of i, one for each caller of the DLL.

A non-reentrant pointer variable cannot take an address as an initializer: the compiler will treat the variable as reentrant if necessary (in other words, it will ignore the pragma). Initializers for non-reentrant variables should be compile-time constants. Due to code relocation during execution time, an address in a program that has both reentrant and non-reentrant variables is never considered a compile-time constant. This restriction includes the addresses of string literals.

Examples

The following program fragment shows how to use the `#pragma variable` directive to force an external program variable to be part of a program that includes executable code and constant data.

```c
#pragma variable(rates, norent)
extern float rates[5] = { 3.2, 83.3, 13.4, 3.6, 5.0 };
extern float totals[5];
int main(void) {
    :
}
```

In this example, you compile the source file with the RENT option. The executable code includes the variable rates because `#pragma variable(rates, norent)` is specified. The writeable static area includes

476  z/OS V1R13.0 XL C/C++ Language Reference
the variable totals. Each user has a personal copy of the array totals, and all users of the program share the array rates. This sharing may yield a performance and storage benefit.

Related information
• The RENT option in the z/OS XL C/C++ User's Guide.

#pragma wsizeof
Category
"Portability and migration" on page 417

Purpose
Toggles the behavior of the sizeof operator between that of a compiler prior the C/C++ for MVS/ESA V3R2 and the z/OS XL C/C++ compiler.

When the sizeof operator was applied to a function return type, older z/OS C and C++ compilers returned the size of the widened type instead of the original type. For example, in the following code fragment, using the older compilers, i has a value of 4.

```c
char foo();
i = sizeof foo();
```

Using the z/OS XL C/C++ compiler, i has a the value of 1, which is the size of the original type, char.

Syntax
```
#pragma wsizeof(on)
```

Defaults
The sizeof operator returns the original type for function return types.

Parameters
on Enables the old compiler behavior of the sizeof operator, so that the widened size is returned for function return types.
resume Re-enables the normal behavior of the sizeof operator.

Usage
You can use this pragma in old header files where you require the old behavior of the sizeof operator. By guarding the header file with a #pragma wsizeof(on) at the start of the header, and a #pragma wsizeof(resume) at the end, you can use the old header file with new applications.

The compiler will match on and resume throughout the entire compilation unit. That is, the effect of the pragma can extend beyond a header file. Ensure the on and resume pragmas are matched in your compilation unit.

The pragma only affects the use of sizeof on function return types. Other behaviors of sizeof remain the same.

Note: Dangling the resume pragma leads to undefined behavior. The effect of an unmatched on pragma can extend to the end of the source file.
IPA effects

During the IPA compile step, the size of each function return value is resolved during source processing. The IPA compile and link steps do not alter these sizes. The IPA object code from translation units with different \texttt{wsizeof} settings is merged together during the IPA link step.

Related information

- The \texttt{WSIZEOF} option in the \textit{z/OS XL C/C++ User's Guide}.

\#pragma XOPTS

Category

"Language element control" on page 414

Purpose

Passes suboptions directly to the CICS integrated translator for processing CICS statements embedded in C/C++ source code.

Syntax

\begin{verbatim}
#pragma XOPTS (suboptions)
\end{verbatim}

Defaults

Not applicable.

Parameters

\begin{itemize}
\item \textbf{XOPTS}
  
  Must be specified in all uppercase.

\item \textit{suboptions}

  Are options to be passed to the CICS integrated translator.
\end{itemize}

Usage

The directive is only valid when the CICS compiler option is in effect. It must appear before any C/C++ or CICS statements in the source, and must appear at file scope (C) or global namespace scope (C++).

Note that if you invoke the compiler with any of the preprocessing-only options, the directive will be preserved in the preprocessed output.

Related information

For detailed information on acceptable embedded CICS statements and preprocessed output, see the description of the CICS compiler option in the \textit{z/OS XL C/C++ User's Guide}. 
Chapter 19. Compiler predefined macros

Predefined macros can be used to conditionally compile code for specific compilers, specific versions of compilers, specific environments and/or specific language features.

Predefined macros fall into several categories:

- "General macros"
- "Macros related to the platform" on page 482
- "Macros related to compiler features" on page 482

"Examples of predefined macros" on page 492 show how you can use them in your code.

General macros

The following predefined macros are always predefined by the compiler. Unless noted otherwise, all the following macros are protected, which means that the compiler will issue a warning if you try to undefine or redefine them.

Table 42. General predefined macros

<table>
<thead>
<tr>
<th>Predefined macro name</th>
<th>Description</th>
<th>Predefined value</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>FUNCTION</strong></td>
<td>Indicates the name of the function currently being compiled.</td>
<td>A character string containing the name of the function currently being compiled.</td>
</tr>
<tr>
<td><strong>LIBREL</strong></td>
<td>Indicates the Language Environment library level under which the compiler is running.</td>
<td>The return value of a compiler call to the librel library function.</td>
</tr>
<tr>
<td><strong>ptr31</strong></td>
<td>Expands to the pointer qualifier __ptr32. Not protected.</td>
<td>__ptr32</td>
</tr>
<tr>
<td>__PTR32</td>

<td></td>
<td>(MMMM) Represents the modification number</td>
</tr>
<tr>
<td></td>
<td></td>
<td>The value of the _TARGET_LIB_ macro depends on the setting of the TARGET compiler option, which allows you to specify the run-time environment and release for the generated object module. The _TARGET_LIB_ macro is set as follows:</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x410D0000 (for zOSV1R13 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x410C0000 (for zOSV1R12 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x410B0000 (for zOSV1R11 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x410A0000 (for zOSV1R10 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41090000 (for zOSV1R9 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41080000 (for zOSV1R8 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41070000 (for zOSV1R7 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41060000 (for zOSV1R6 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41050000 (for zOSV1R5 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41040000 (for zOSV1R4 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41030000 (for zOSV1R3 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41020000 (for zOSV1R2 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x41010000 (for zOSV1R1 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- 0x220A0000 (for OSV2R10 TARGET suboption)</td>
</tr>
<tr>
<td></td>
<td></td>
<td>- (0xnnnnnnnnn) (for (0xnnnnnnnnn) TARGET suboption)</td>
</tr>
</tbody>
</table>

If the TARGET suboption is specified as a hexadecimal string literal, this macro is also defined to that literal.
Macros indicating the z/OS XL C/C++ compiler product

Macros related to the z/OS XL C/C++ compiler are always predefined, and are protected (the compiler issues a warning if you try to undefine or redefine them). You can specify the SHOWMACROS(PRE) compiler option to view predefined macro definitions in preprocessed output.

Table 43. Compiler product predefined macros

<table>
<thead>
<tr>
<th>Predefined macro name</th>
<th>Description</th>
<th>Predefined value</th>
</tr>
</thead>
</table>
| __COMPILER_VER__ | Indicates the version of the compiler. | A hexadecimal integer in the format $PVRRM$, where:
| | $P$ Represents the compiler product |
| | • 0 for C/370 |
| | • 1 for IBM AD/Cycle® C/370 and C/C++ for MVS/ESA |
| | • 2 for OS/390 C/C++ |
| | • 4 for z/OS Release 2 and later |
| | $V$ Represents the version number |
| | $RR$ Represents the release number |
| | $MMMM$ Represents the modification number |
| __IBMC__ | Indicates the level of the XL C compiler. | An integer in the format $PVRM$, where:
| | $P$ Represents the compiler product |
| | • 0 for C/370 |
| | • 1 for AD/Cycle C/370 and C/C++ for MVS/ESA |
| | • 2 for OS/390 C/C++ |
| | • 4 for z/OS Release 2 and later |
| | $V$ Represents the version number |
| | $RR$ Represents the release number |
| | $M$ Represents the modification number |
| __IBMCPP__ | Indicates the level of the XL C++ compiler. | An integer in the format $PVRRM$, where:
| | $P$ Represents the compiler product |
| | • 0 for C/370 |
| | • 1 for AD/Cycle C/370 and C/C++ for MVS/ESA |
| | • 2 for OS/390 C/C++ |
| | • 4 for z/OS Release 2 and later |
| | $V$ Represents the version number |
| | $RR$ Represents the release number |
| | $M$ Represents the modification number |
Macros related to the platform

The following predefined macros are provided to facilitate porting applications between platforms. All platform-related predefined macros are unprotected and can be undefined or redefined without warning unless otherwise specified.

Table 44. Platform-related predefined macros

</tr>
</tbody>
</table>

Macros related to compiler features

Feature-related macros are predefined according to the setting of specific compiler options or pragmas. Unless noted otherwise, all feature-related macros are protected (the compiler will issue a warning if you try to undefine or redefine them).

Feature-related macros are discussed in the following sections:
- "Macros related to compiler option settings"
- "Macros related to language levels" on page 488

Macros related to compiler option settings

The following macros can be tested for various features, including source input characteristics, output file characteristics, and optimization. All of these macros are predefined by a specific compiler option or suboption, or any invocation or pragma that implies that suboption. If the suboption enabling the feature is not in effect, then the macro is undefined.

See the description of each option in the z/OS XL C/C++ User’s Guide for detailed information about the option.

## Macros related to language levels

The following macros can be tested for C99 features, features related to GNU C or C++, and other IBM language extensions. All of these macros are predefined to a value of 1 by a specific language level, represented by a suboption of the LANGLVL compiler option, or any invocation or pragma that implies that suboption. If the suboption enabling the feature is not in effect, then the macro is undefined. For descriptions of the features related to these macros, see the *z/OS XL C/C++ Language Reference*.

### Examples of predefined macros

This example illustrates use of the `__FUNCTION__` and the `__C99__FUNC__` macros to test for the availability of the C99 `__func__` identifier to return the current function name:

```c
#include <stdio.h>

#if defined(__C99__FUNC__)
#define PRINT_FUNC_NAME() printf(" In function %s \n", __func__);
#elif defined(__FUNCTION__)
#define PRINT_FUNC_NAME() printf(" In function %s \n", __FUNCTION__);
```
#else
#define PRINT_FUNC_NAME() printf (" Function name unavailable\n");
#endif

void foo(void);

int main(int argc, char **argv)
{
    int k = 1;
    PRINT_FUNC_NAME();
    foo();
    return 0;
}

void foo (void)
{
    PRINT_FUNC_NAME();
    return;
}

The output of this example is:
In function main
In function foo

This example illustrates use of the __FUNCTION__ macro in a C++ program with virtual functions.

CCNX08C

#include <stdio.h>
class X { public: virtual void func() = 0;};
class Y : public X {
    public: void func() { printf("In function %s \n", __FUNCTION__);}
};

int main() {
    Y aaa;
    aaa.func();
}

The output of this example is:
In function Y::func()
Chapter 20. The IBM XL C++ language extensions

The IBM XL C++ extensions to Standard C++ include:

- Unicode support
- C++0x compatibility

General IBM extensions

The following feature is enabled with the `LANGLVL(COMPAT366 | EXTENDED)` option. It can also be enabled or disabled by a specific compiler option, listed in the following table:

<table>
<thead>
<tr>
<th>Language feature</th>
<th>Discussed in:</th>
<th>Individual option controls</th>
</tr>
</thead>
<tbody>
<tr>
<td>Non-C99 IBM <code>long long</code> extension</td>
<td>“Types of integer literals outside of C99 and C++0x” on page 17</td>
<td>[NO]LONGLONG</td>
</tr>
</tbody>
</table>

Extensions for C++0x compatibility

**Note:** C++0x is a new version of the C++ programming language standard. This is a draft standard and has not been officially adopted in its entirety. The implementation of C++0x is based on IBM's interpretation of the draft C++0x standard and is subject to change at any time without notice. IBM makes no attempt to maintain compatibility with earlier releases and therefore the C++0x language extension should not be relied on as a stable programming interface.

The following features are part of a continual phased release process leading towards full compliance with C++0x. They can be enabled by using the `LANGLVL(EXTENDED0X)` group option. You can also use specific compiler options to enable or disable these features. See the following table.

<table>

<td>&quot;Trailing return type (C++0x)&quot; on page 202</td>
<td>LANGLVL((NO)AUTOTYPEDEDUCTION)</td>
</tr>
<tr>
<td>Variadic templates</td>
<td>&quot;Variadic templates (C++0x)&quot; on page 356</td>
<td>LANGLVL((NO)VARIADIC[TEMPLATES])</td>
</tr>
</tbody>
</table>

Notes:

- You can also use the LANGLVL(EXTENDED) group option to enable the explicit instantiation declarations feature.
- If you try to use a C++0x feature when the feature is not enabled, the compiler issues an information message that follows a syntax error message. The information message indicates how to turn on the C++0x feature to recover from the syntax error. The involved C++0x features are listed as follows:
  - C99 preprocessor features adopted in C++0x
    - Mixed string literal concatenation
    - The __STDC_HOSTED__ macro
  - Delegating constructors
  - Explicit conversion operators
  - Inline namespace definitions
  - Scoped enumerations
  - Variadic templates

Extensions for GNU C compatibility

The following subset of the GNU C language extensions are enabled with the LANGLVL(EXTENDED) option, which is the default language level. These extensions can also be enabled or disabled by specific compiler options, which are listed in the below table:

Table 48. Default IBM XL C++ extensions for compatibility with GNU C, with individual option controls

<table>
<thead>
<tr>
<th>Language feature</th>
<th>Discussed in:</th>

<td>LANGLVL((NO)GNU_COMPUTEDGOTO)</td>
</tr>
</tbody>
</table>

Extension of #endif

The C/C++ language standards do not allow extra text after #endif or #else. IBM XL C and XL C/C++ compilers comply with the standards. When you are porting code from a compiler that allows extra text after #endif or #else, you can specify option LANGLVL(TEXTAFTERENDIF) to suppress the warning message that is emitted.

It is common to put text after #else and #endif. One common use is to comment on what is being tested by the corresponding #if or ifndef. For example:
In this case, if you want the compiler to be silent about this deviation from the standards, you can suppress the message by specifying option LANGLEVEL(TEXTAFTERENDIF), while allowing the message to be emitted in other contexts, for example, if there is additional text after #undef.

The suboption TEXTAFTERENDIF can be specified with any of the supported language levels. In almost all cases the default for this suboption is LANGLEVEL(NOTEXTAFTERENDIF), indicating that a message will be emitted if there is any extraneous text after #else or #endif. The one exception is in the C compiler, when the language level is "classic". In this case, the default for the suboption is LANGLEVEL(TEXTAFTERENDIF), because this language level already allows extra text after #else or #endif without generating a message.

---

**Extending the lifetime of C++ temporaries**

The C++ Language Standard describes the lifetime of temporaries in section *Temporary Object* [class.temporary]. When you are porting an application from a compiler that implements late temporary destruction, you might need to extend the lifetime of C++ temporaries beyond which is specified in the C++ Language Standard. In this way, you can closely replicate the non-standard compliant behavior of your previous compiler.

It is possible that a program incorrectly depends on resources, which might have been previously released during destruction of a temporary. See "Example 1" on page 498. In such cases, a compiler that incorrectly destroys a temporary later than it should be, might execute the resulting program in the desired way. Such problems might surface during porting, when correct insertion of temporary destructors yields invalid access to a released resource.

With IBM XL C/C++ compilers, you can extend the lifetime of temporaries to reduce migration difficulty. This is enabled by specifying option LANGLEVEL(TEMPSASLOCALS). When enabled, the lifetime of temporaries is extended as though such temporaries are treated as local variables declared in the inner-most containing lexical scope. Most temporaries will be destroyed when their enclosing scope is exited, rather than when the enclosing full-expression is completed. See "Example 2" on page 499.

**Default**

LANGLEVEL(NOTEMPSASLOCALS)

The compiler listing emits LANGLEVEL(TEMPSASLOCALS) when the feature is enabled, and LANGLEVEL(NOTEMPSASLOCALS) when the feature is disabled.

**Usage**

- Temporaries constructed in the condition statement of an if-statement should be destroyed at the end of execution of the if-statement. Temporary destruction is delayed until after any else-if or else blocks, as would a variable declared in the condition statement.
- Temporaries constructed in the condition of a switch statement should be destroyed at the end of execution of the switch statement.
- Temporaries for which the inner-most enclosing lexical scope is the lexical scope of a switch statement should be handled in the standard compliant way.
- Temporaries constructed in the condition or increment expressions of a loop must be destroyed in the standard compliant way.
When LANGLVL(ANSIFOR) is in effect, temporaries constructed in the for-init statement must be destroyed at the end of execution of the for-loop. When LANGLVL(NOANSIFOR) is in effect, temporaries constructed in the for-init statement must be destroyed at the end of execution of the inner-most lexical block containing the for-loop.

Temporaries constructed at namespace scope must be handled in the standard compliant way. See “Example 3” on page 500.

When INFO(POR) is in effect, and the lifetime of a temporary would otherwise be extended by this feature, and the inner-most containing lexical scope of the temporary contains a label definition that follows the construction of a temporary, that temporary shall be handled in the standard compliant way. See “Example 4” on page 500.

When INFO(POR) is in effect, and the lifetime of a temporary would otherwise be extended by this feature, and the inner-most containing lexical scope of the temporary contains a computed goto that follows the construction of a temporary, that temporary shall be handled in the standard compliant way. See “Example 5” on page 500.

Example 1

```c
>cat myString.h
#include <string>
#define MY_SL_STD(MY_NAME) ::std::MY_NAME
class MYString
{
    public:
        // common constructors
        MYString() {}
        MYString(const MY_SL_STD(string&) data) : data_(data) {}
        MYString(MYString& str) : data_(str.data_) {}
        MYString(MYString&& str) : data_(str) {}
        MYString(char c, size_t N) : data_(N, c) {}
        MYString(const char* s) : data_(s) {}
        MYString(const char* s, size_t N) : data_(s,N) {}
        // constructor explicitly from char
        MYString(char c) : data_(1,c) {}
        ~MYString() {}
        const char* data() const { return data_.c_str(); }
        // Type conversion:
        operator const char*() const { return data_.c_str(); }
    }
}
```

Example 1

```c
>cat myString.C
#include <iostream.h>
#include "mystring.h"
class A
{
    public:
        A(const char * str_)
        {
            strcpy(str, str_);
        }
        MYString getStr()
        {
            return str;
        }
        void print()
        {
            cout<<"object A "<< str <<endl;
        }
```

Example 1
private:
   char str[2000];
};

void foo(const char* s)
{
   cout<<"foo: "<<s <<-end1;
}

int main()
{
   A a("This is a test");
a.print();
   const char * p = (const char*) a.getStr();
cout <<"p= " << p <<-end1;
   return (0);
}

In this example, the char array in the object is converted to a MYString to pass it out of getStr. The
method A::getStr would change to A::MYString object. Whenever the getStr is used, the program will
generate incorrect results, thus indicating a problem.

When the call to a getStr() is made, the method takes the str buffer and constructs a MYString object. It is
a MYString object that is returned, and the code calls a MYString method to convert to a const char *. This
method returns a pointer to a temporary copy of the string, "This is a test." Once the pointer has been
received and stored into the p variable, the destructor for the temporary object is called. This is where the
memory referenced by p now no longer contains "This is a test." Since the character string is a temporary
copy, the string doesn't exist anywhere except in the original location inside the object. Any use of the p
will access garbage.

Because the creation of these temporary objects uses dynamic memory, you cannot really depend upon
the object still being valid and containing the same contents any longer than the statement in which it is
used.

Example 2
#include<cstdio>
struct S {
   S() { printf("S::S() ctor at 0x%lx.\n", this); }
   S(const S& from) { printf("S::S(const S&) copy ctor at 0x%lx.\n", this); }
   ~S() { printf("S::~S() dtor at 0x%lx.\n", this); }
} s1;
void foo(S s) { }
int main()
{
   foo(s1);
   printf("hello world.\n");
   return 0;
}

The C++ Standard compliant output of this program is:
S::S() ctor at 0x20000d7c.
S::S(const S&) copy ctor at 0xff221e0.
S::~S() dtor at 0xff221e0.
hello world.
S::~S() dtor at 0x20000d7c.

Note that the temporary copy constructed for the call to foo is destroyed upon return from foo. When the
lifetime of the temporary is extended, the output of this program shall be:
The temporary copy constructed for the call to foo is now destroyed when the enclosing scope is exited. It is therefore destroyed after the print of "hello world."

Example 3

```c
struct S {  
    S(int);  
    ~S();  
    int i;  
} s1(42);  

int main() {  
    S s1;  
    bar(s1);  
    s1.i = 42;  // s1 should be referenced after call to bar or a temporary may not  
               // be constructed.  
    return 0;  // the temporary would otherwise be destroyed here.  
}  
```

Example 5

```c
void foo(void *p) {  
    bar(s1);  // the temporary for argument s of bar is not affected  
    goto *p;  
}  
```
Binding an rvalue to a non-const reference

The C++ Standard (2003) indicates that an rvalue can only be bound to a const reference. Non-compliant compilers might allow a non-const reference to be bound to an rvalue. When you are porting code to IBM XL C/C++ compiler, you can specify option LANGLVL(COMPATRVALUEBINDING) to instruct the compiler to allow a non-const reference to bind to an rvalue of a user-defined type where an initializer is not required.

With the option INFO(POR) specified, when the compiler chooses such a binding, the following informational message is emitted.

(I) An rvalue has been bound to a reference to a non-const type.

You can correct the cases where the message was emitted so that your code is standard compliant.

Default

The default is LANGLVL(NOCOMPATRVALUEBINDING).

Rules

IBM XL C/C++ compiler does not allow rvalues of built-in type to bind to a non-const reference, or rvalues to bind to non-const references that are class members.
Appendix A. C and C++ compatibility on the z/OS platform

This information pertains to the differences between C and C++ that apply specifically to the z/OS platform. The contents describe the constructs that are found in both ISO C and ISO C++, but which are treated differently in the two languages.

String initialization

In C++, when you initialize character arrays, a trailing '\0' (zero of type char) is appended to the string initializer. You cannot initialize a character array with more initializers than there are array elements.

In C, space for the trailing '\0' can be omitted in this type of initialization.

The following initialization, for instance, is not valid in C++:
char v[3] = "asd"; /* not valid in C++, valid in C */

because four elements are required. This initialization produces an error because there is no space for the implied trailing '\0' (zero of type char).

Class/structure and typedef names

In C++, a class or structure and a typedef cannot both use the same name to refer to a different type within the same scope (unless the typedef is a synonym for the class or structure name). In C, a typedef name and a struct tag name declared in the same scope can have the same name because they have different name spaces. For example:

```c
int main ()
{
    typedef double db;
    struct db; /* error in C++, valid in C */
    typedef struct st st; /* valid C and C++ */
}
```

The same distinction applies within class/structure declarations. For example:

```c
int main ()
{
    typedef double db;
    struct st
    {
        db x;
        double db; /* error in C++, valid in C */
    };
}
```

Class/structure and scope declarations

In C++, a class declaration introduces the class or structure name into the scope where it is declared and hides any object, function, or other declaration of that name in an outer scope. In C, an inner scope declaration of a struct name does not hide an object or function of that name in an outer scope. For example:

double db;
int main ()
{
    struct db        /* hides double object db in C++ */
const object initialization

In C++, const objects must be initialized. In C, they can be left uninitialized.

Definitions

An object declaration is a definition in C++. In C, it is a declaration (also known as a tentative definition). For example:

```c
int i;
```

In C++, a global data object must be defined only once. In C, a global data object can be declared several times without using the extern keyword.

In C++, multiple definitions for a single variable cause an error. A C compilation unit can contain many identical declarations for a variable.

Definitions within return or argument types

In C++, types may not be defined in return or argument types. C allows such definitions. For example, the following declarations produce errors in C++, but are valid declarations in C:

```c
void print(struct X { int i; } x); /* error in C++ */
enum count{one, two, three} counter(); /* error in C++ */
```

Enumerator type

An enumerator has the same type as its enumeration in C++. In C, an enumeration has type int.

Enumeration type

The assignment to an object of enumeration type with a value that is not of that enumeration type produces an error in C++. In C, an object of enumeration type can be assigned values of any integral type.

Function declarations

In C++, all declarations of a function must match the unique definition of a function. C has no such restriction.

Functions with an empty argument list

Consider the following function declaration:

```c
int f();
```

In C++, this function declaration means that the function takes no arguments. In C, it could take any number of arguments, of any type.

Global constant linkage

In C++, an object declared const has internal linkage, unless it has previously been given external linkage. In C, it has external linkage.
Jump statements

C++ does not allow you to jump over declarations containing initializations. C does allow you to use jump
statements for this purpose.

Keywords

C++ contains some additional keywords not found in C. C programs that use these keywords as identifiers
are not valid C++ programs:

Table 49. C++ keywords

</tbody>
</table>

main() recursion

In C++, main() cannot be called recursively and cannot have its address taken. C allows recursive calls
and allows pointers to hold the address of main().

Names of nested classes/structures

In C++, the name of a nested class is local to its enclosing class. In C, the name of the nested structure
belongs to the same scope as the name of the outermost enclosing structure.

Pointers to void

C++ allows void pointers to be assigned only to other void pointers. In C, a pointer to void can be
assigned to a pointer of any other type without an explicit cast.

Prototype declarations

C++ requires full prototype declarations. C allows nonprototyped functions.

Return without declared value

In both C and C++, the function main() must be declared to return a value of type int. In C++, if no value
is explicitly returned from function main() by means of a return statement and if program execution
reaches the end of function main() (that is, the program does not terminate due to a call to exit(),
std::terminate(), or a similar function), then the value 0 is implicitly returned. A return (either explicit or
implicit) from all other functions that are declared to return a value must return a value. In C, a function
that is declared to return a value can return with no value, with unspecified results.

__STDC__ macro

The predefined macro variable __STDC__ is defined for C++, and it has the integer value 0 when it is used
in an if statement, indicating that the C++ language is not a proper superset of C, and that the compiler
does not conform to C. In C, __STDC__ has the integer value 1.
Appendix B. Common Usage C language level for the z/OS platform

The X/Open Portability Guide (XPG) Issue 3 describes a C language definition referred to as Common Usage C. This language definition is roughly equivalent to K&R C, and differs from the ISO C language definition. It is based on various C implementations that predate the ISO standard.

Common Usage C is supported with the LANGLVL(COMMONC) compiler option or the #pragma langlvl(commonc) directive. These cause the compiler to accept C source code containing Common Usage C constructs.

Many of the Common Usage C constructs are already supported by #pragma langlvl(extended). The following language elements are different from those accepted by #pragma langlvl(extended).

- Standard integral promotions preserve sign. For example, unsigned char or unsigned short are promoted to unsigned int. This is functionally equivalent to specifying the UPCONV compiler option.
- Trigraphs are not processed in string or character literals. For example, consider the following source line:
  ```
  ??=define STR "??= not processed"
  ```
  The above line gets preprocessed to:
  ```
  #define STR "??= not processed"
  ```
  - The sizeof operator is permitted on bitfields. The result is the size of an unsigned int (4).
  - Bitfields other than type int are permitted. The compiler issues a warning and changes the type to unsigned int.
  - Macro parameters found within single or double quotation marks are expanded. For example, consider the following source lines:
    ```
    #define STR(AAA) "String is: AAA"
    #define ST STR(BBB)
    ```
    The above lines are preprocessed to:
    ```
    "String is: BBB"
    ```
    - Macros can be redefined without first being undefined (that is, without an intervening #undef). An informational message is issued saying that the second definition is used.
    - The empty comment (/* */) in a function-like macro is equivalent to the ISO token concatenation operator ##.

The LANGLVL compiler option is described in z/OS XL C/C++ User's Guide. The #pragma langlvl is described in #pragma langlvl directive (C only) on page 441.
Appendix C. Conforming to POSIX 1003.1

For a description of how the z/OS UNIX System Services implementation meets the criteria, see IBM Corporation Conformance Statement.
Appendix D. Implementation-defined behavior

This information describes how the z/OS XL C/C++ compilers define some of the implementation-specific behavior from the ISO C and C++ standards. In-depth usage information is provided in z/OS XL C/C++ User’s Guide and z/OS XL C/C++ Programming Guide.

Identifiers

The number of significant characters in an identifier with no external linkage:
• 1024

The number of significant characters in an identifier with external linkage:
• 1024 with the compile-time option LONGNAME specified
• 8 otherwise
  The C++ compiler truncates external identifiers without C++ linkage after 8 characters if the NOLONGNAME compiler option or pragma is in effect.

Case sensitivity of external identifiers:
• The binder accepts all external names up to 1024 characters, and is optionally case sensitive. The linkage editor accepts all external names up to 8 characters, and may not be case sensitive, depending on whether you use the NOLONGNAME compiler option or pragma. When the NOLONGNAME option is used, all external names are truncated to 8 characters. As an aid to portability, identifiers that are not unique after truncation are flagged as an error.

Characters

Source and execution characters which are not specified by the ISO standard:
• The caret (^) character in ASCII (bitwise exclusive OR symbol) or the equivalent not (¬) character in EBCDIC.
• The vertical broken line (¦) character in ASCII which may be represented by the vertical line (|) character on EBCDIC systems.

Shift states used for the encoding of multibyte characters:
• The shift states are indicated with the SHIFTOUT (hex value \x0E) characters and SHIFTIN (hex value \x0F).

The number of bits that represent a single-byte character:
• 8 bits

The mapping of members of the source character set (characters and strings) to the execution character set:
• The same code page is used for the source and execution character set.

The value of an integer character constant that contains a character/escape sequence not represented in the basic execution character set:
• A warning is issued for an unknown character/escape sequence and the char is assigned the character following the back slash.

The value of a wide character constant that contains a character/escape sequence not represented in the extended execution character set:
• A warning is issued for the unknown character/escape sequence and the wchar_t is assigned the wide character following the back slash.
The value of an integer character constant that contains more than one character:
- The lowest four bytes represent the character constant.

The value of a wide character constant that contains more than one multibyte character:
- The lowest four bytes of the multibyte characters are converted to represent the wide character constant.

Equivalent type of char: signed char, unsigned char, or user-defined:
- The default for char is unsigned

Sequence of white-space characters (excluding the new-line):
- Any spaces or comments in the source program are interpreted as one space.

String conversion

Additional implementation-defined sequence forms that can be accepted by stdrtod, stdrtol and stdrtoul functions in other than the C locale:
- None

Integers

</tr>
</tbody>
</table>

The result of converting an integer to a signed char:
- The lowest 1 byte of the integer is used to represent the char

The result of converting an integer from a shorter signed integer:
- The lowest 2 bytes of the integer are used to represent the short int.

The result of converting an unsigned integer to a signed integer of equal length, if the value cannot be represented:
- The bit pattern is preserved and the sign bit has no significance.

The result of bitwise operations (|, &, ^) on signed int:
- The representation is treated as a bit pattern and 2's complement arithmetic is performed.

The sign of the remainder of integer division if either operand is negative:
- The remainder is negative if exactly one operand is negative.

The result of a right shift of a negative-valued signed integral type:
- The result is sign-extended and the sign is propagated.
Floating-point numbers

</tr>
</tbody>
</table>

The following is the direction of truncation (or rounding) when you convert an integer number to an IBM z/Architecture hexadecimal floating-point number, or to an IEEE binary floating-point number:

- **IBM z/Architecture hexadecimal format:**
  - When the floating-point cannot exactly represent the original value, the value is truncated.
  - When a floating-point number is converted to a narrower floating-point number, the floating-point number is truncated.

- **IEEE binary format:**
  - The rounding direction is determined by the ROUND compiler option. The ROUND option only affects the rounding of floating-point values that the z/OS XL C/C++ compiler can evaluate at compile time. It has no effect on rounding at run time.

### C/C++ data mapping

The z/Architecture has the following boundaries in its memory mapping:

- **Byte**
- **Halfword**
- **Fullword**
- **Doubleword**

The code that is produced by the C/C++ compiler places data types on natural boundaries. Some examples are:

- **Byte boundary for** char, _Bool, bool, and decimal (n, p)
- **Halfword boundary for** short int
- **Fullword boundary for** int, long int, pointers, float, and float _Complex
- **Doubleword boundary for** double, long double, double _Complex, and long double _Complex

For each external defined variable, the z/OS XL C/C++ compiler defines a writeable static data instance of the same name. The compiler places other external variables, such as those in programs that you compile with the NORENT compiler option, in separate csects that are based on their names.

### Arrays and pointers

The type of **size_t**:

- **unsigned int** in 32–bit mode
- **unsigned long** in 64–bit mode

The type of **ptrdiff_t**:

- **int** in 32–bit mode
- **long** in 64–bit mode
The result of casting a pointer to an integer:
- The bit patterns are preserved.

The result of casting an integer to a pointer:
- The bit patterns are preserved.

**Registers**

The effect of the `register` storage class specifier on the storage of objects in registers:
- The register storage class indicates to the compiler that a variable in a block scope data definition or a parameter declaration is heavily used (such as a loop control variable). It is equivalent to `auto`, except that the compiler might, if possible, place the variable into a machine register for faster access.

**Structures, unions, enumerations, bit fields**

The result when a member of a union object is accessed using a member of a different type:
- The result is undefined.

The alignment/padding of structure members:
- If the structure is not packed, then padding is added to align the structure members on their natural boundaries. If the structure is packed, no padding is added.

The padding at the end of structure/union:
- Padding is added to end the structure on its natural boundary. The alignment of the structure or union is that of its strictest member.

The type of an `int` bit field (`signed int`, `unsigned int`, user defined):
- The default is `unsigned`.

The order of allocation of bit fields within an `int`:
- Bit fields are allocated from low memory to high memory. For example, 0x12345678 would be stored with byte 0 containing 0x12, and byte 3 containing 0x78.

The rule for bit fields crossing a storage unit boundary:
- Bit fields can cross storage unit boundaries.

The integral type that represents the values of an enumeration type:
- Enumerations can have the type `char`, `short` or `long` and be either `signed` or `unsigned` depending on their smallest and largest values.

**Declarators**

The maximum number of declarators (pointer, array, function) that can modify an arithmetic, structure, or union type:
- The only constraint is the availability of system resources.

**Statements**

The maximum number of case values in a switch statement:
- Because the case values must be integers and cannot be duplicated, the limit is `INT_MAX`. 
Preprocessing directives

Value of a single-character constant in a constant expression that controls conditional inclusion:
- Matches the value of the character constant in the execution character set.

Such a constant may have a negative value:
- Yes

The method of searching include source files (<...>):
- See z/OS XL C/C++ User’s Guide.

The method of searching quoted source files:
- User include files can be specified in double quotes. See z/OS XL C/C++ User’s Guide.

The mapping between the name specified in the include directive and the external source file name:
- See z/OS XL C/C++ User’s Guide.

The definitions of __DATE__ and __TIME__ when date and time of translation is not available:
- For z/OS XL C/C++, the date and time of translation are always available.

Translation limits

System-determined means that the limit is determined by your system resources.

### Note:

1. LONG_MAX is the limit for automatic variables only. For all other variables, the limit is 16 megabytes.
Appendix E. Accessibility

Accessibility features help a user who has a physical disability, such as restricted mobility or limited vision, to use software products successfully. The major accessibility features in z/OS enable users to:

- Use assistive technologies such as screen readers and screen magnifier software
- Operate specific or equivalent features using only the keyboard
- Customize display attributes such as color, contrast, and font size

Using assistive technologies

Assistive technology products, such as screen readers, function with the user interfaces found in z/OS. Consult the assistive technology documentation for specific information when using such products to access z/OS interfaces.

Keyboard navigation of the user interface

Users can access z/OS user interfaces using TSO/E or ISPF. Refer to z/OS TSO/E Primer, z/OS TSO/E User's Guide, and z/OS ISPF User's Guide Vol I for information about accessing TSO/E and ISPF interfaces. These guides describe how to use TSO/E and ISPF, including the use of keyboard shortcuts or function keys (PF keys). Each guide includes the default settings for the PF keys and explains how to modify their functions.

z/OS information

z/OS information is accessible using screen readers with the BookServer/Library Server versions of z/OS books in the Internet library at:

http://www.ibm.com/systems/z/os/zos/bkserv/
